#### SUMMARY

High-dimensional data are often most plausibly generated from distributions with complex structure and leptokurtosis in some or all components. Covariance and precision matrices provide a useful summary of such structure, yet the performance of popular matrix estimators typically hinges upon a sub-Gaussianity assumption. This paper presents robust matrix estimators whose performance is guaranteed for a much richer class of distributions. The proposed estimators, under a bounded fourth moment assumption, achieve the same minimax convergence rates as do existing methods under a sub-Gaussianity assumption. Consistency of the proposed estimators is also established under the weak assumption of bounded  $2 + \varepsilon$  moments for  $\varepsilon \in (0, 2)$ . The associated convergence rates depend on  $\varepsilon$ .

Some key words: Constrained  $\ell_1$ -minimization; Leptokurtosis; Minimax rate; Robustness; Thresholding.

#### 1. INTRODUCTION

Covariance and precision matrices play a central role in summarizing linear relationships among variables. Our focus is on estimating these matrices when their dimension is large relative to the number of observations. Besides being of interest in themselves, estimates of covariance and precision matrices are used for numerous procedures from classical multivariate analysis, including linear regression.

Consistency is achievable under structural assumptions provided regularity conditions are met. For instance, under the assumption that all rows or columns of the covariance matrix belong to a sufficiently small  $\ell_q$ -ball around zero, thresholding (Bickel & Levina, 2008; Rothman et al., 2008) or its adaptive counterpart (Cai & Liu, 2011) gives consistent estimators of the covariance matrix in the spectral norm for data from a distribution with sub-Gaussian tails. For precision matrix estimation, the same sparsity assumption on the precision matrix motivates the use of the constrained  $\ell_1$ -minimizer of Cai et al. (2011) or its adaptive counterpart (Cai et al., 2016), both of which are consistent in spectral norm under the same sub-Gaussianity condition. Under sub-Gaussianity, Cai & Liu (2011) and Cai et al. (2016) showed that in high-dimensional regimes the adaptive thresholding estimator and adaptive constrained  $\ell_1$ -minimization estimator are minimax optimal within the classes of covariance or precision matrices satisfying their sparsity constraint.

Since sub-Gaussianity is often too restrictive in practice, we seek new procedures that can achieve the same minimax optimality when data are leptokurtic. Inspection of the proofs of Bickel & Levina (2008), Cai & Liu (2011) and Cai et al. (2016) reveals that sub-Gaussianity is needed because their methods are built on the sample covariance matrix, which requires the assumption to guarantee its optimal performance. Here we show that minimax optimality is achievable within a larger class of distributions if the sample covariance matrix is replaced by a robust pilot estimator, thus providing a unified theory for covariance and precision matrix estimation based on general pilot estimators. We also show how to construct pilot estimators that have the required elementwise convergence rates of (1) and (2) below. Within a much larger class of distributions with bounded fourth moment, it is shown that an estimator obtained by regularizing a robust pilot estimator attains the minimax rate achieved by existing methods under sub-Gaussianity. The analysis is extended to show that when only bounded  $2 + \varepsilon$  moments exist for  $\varepsilon \in (0, 2)$ , matrix estimators with satisfactory convergence rates are still attainable.

Some related work includes that of Liu et al. (2012) and Xue & Zou (2012), who considered robust estimation of graphical models when the underlying distribution is elliptically symmetric, Fan et al. (2015, 2016a,b), who studied robust matrix estimation in the context of factor models, and Chen et al. (2015) and Loh & Tan (2015), who investigated matrix estimation when the data are contaminated by outliers. The present paper is concerned with efficient estimation of general sparse covariance and precision matrices when only certain moment conditions are assumed.

For a *p*-dimensional random vector X with mean  $\mu$ , let  $\Sigma^* = E\{(X - \mu)(X - \mu)^T\}$  and let  $\tilde{\Sigma} = (\tilde{\sigma}_{uv})$  denote an arbitrary pilot estimator of  $\Sigma^* = (\sigma_{uv}^*)$ , where  $u, v \in [p]$  with [p] standing for  $\{1, \ldots, p\}$ . The key requirement on  $\tilde{\Sigma}$  for optimal covariance estimation is that

$$\Pr\left[\max_{u,v} |\tilde{\sigma}_{uv} - \sigma_{uv}^*| \leqslant C_0 \{(\log p)/n\}^{1/2}\right] \ge 1 - \varepsilon_{n,p},\tag{1}$$

where  $C_0$  is a positive constant and  $\varepsilon_{n,p}$  is a deterministic sequence converging to zero as  $n, p \to \infty$ such that  $n^{-1} \log p \to 0$ . This delivers rates of convergence that match the minimax rates of Cai & Liu (2011) even under violations of their sub-Gaussianity condition, which entails the existence of b > 0 such that  $E(\exp[t\{X_u - E(X_u)\}]) \leq \exp(b^2t^2/2)$  for every  $t \in \mathbb{R}$  and every  $u \in [p]$ . Introduce the sample covariance matrix

$$\hat{\Sigma} = (\hat{\sigma}_{uv}) = n^{-1} \sum_{i=1}^{n} (X_i - \bar{X}) (X_i - \bar{X})^{\mathrm{T}},$$

where  $X_1, \ldots, X_n$  are independent and identically distributed copies of X and  $\bar{X} = n^{-1} \sum_{i=1}^n X_i$ . Proposition 1 shows that  $\hat{\Sigma}$  violates (1) when X is not sub-Gaussian. In other words, the sample covariance does not concentrate exponentially fast in an elementwise sense if sub-Gaussianity is violated.

Similarly, for estimation of the precision matrix  $\Omega^* = (\Sigma^*)^{-1}$ , the optimality of the adaptive constrained  $\ell_1$ -minimization estimator is retained under a pilot estimator satisfying

$$\Pr\left[\max_{u,v} \left| (\tilde{\Sigma}\Omega^* - I_p)_{uv} \right| \leqslant C_0 \{ (\log p)/n \}^{1/2} \right] \ge 1 - \varepsilon_{n,p},$$
(2)

where  $C_0$  and  $\varepsilon_{n,p}$  are as in (1) and  $I_p$  denotes the  $p \times p$  identity matrix. While (2) holds with  $\tilde{\Sigma} = \hat{\Sigma}$  under sub-Gaussianity of X, it fails otherwise.

The following proposition provides a more formal illustration of the unsuitability of  $\tilde{\Sigma} = \hat{\Sigma}$  as a pilot estimator in the absence of sub-Gaussianity.

PROPOSITION 1. Let  $E(|X_uX_v - \sigma_{uv}^*|^{1+\gamma}) \leq 2$  for  $u \neq v$  and some  $\gamma > 0$ . For all distributions of X satisfying this assumption, there is a distribution pr such that for some  $\varepsilon < 1/2$ ,

$$\operatorname{pr}\left\{|\hat{\sigma}_{uv} - \sigma_{uv}^*| > 2^{-1}\varepsilon^{-1/(1+\gamma)}n^{-\gamma/(1+\gamma)}\right\} \geq \varepsilon.$$

This implies that the choice to take the sample covariance as the pilot estimator  $\tilde{\Sigma}$  results in a polynomial rate of convergence, which is slower than the exponential rate of concentration in (1). Instead, we introduce robust pilot estimators in § 4 that satisfy the conditions (1) and (2). These estimators only require  $\max_{1 \le u \le p} E(|X_u|^4) < \infty$ .

Throughout the paper, for a vector  $a = (a_1, \ldots, a_p)^T \in \mathbb{R}^p$ ,  $||a||_1 = \sum_{v=1}^p |a_v|$ ,  $||a||_2 = (\sum_{v=1}^p a_v^2)^{1/2}$  and  $||a||_{\infty} = \max_{1 \le v \le p} |a_v|$ . For a matrix  $A = (a_{uv}) \in \mathbb{R}^{p \times q}$ ,  $||A||_{\max} = \max_{1 \le u \le p, 1 \le v \le q} |a_{uv}|$  is the elementwise maximum norm,  $||A||_2 = \sup_{||x||_2 \le 1} ||Ax||_2$  is the spectral norm, and  $||A||_1 = \max_{1 \le v \le q} \sum_{u=1}^p |a_{uv}|$  is the matrix  $\ell_1$ -norm. We let  $I_p$  denote the  $p \times p$  identity matrix; A > 0 and  $A \ge 0$  mean that A is positive definite and positive semidefinite, respectively. For a square matrix A, we denote its maximum and minimum eigenvalues by  $\lambda_{\max}(A)$  and  $\lambda_{\min}(A)$ , respectively. We also assume that E(X) = 0.

#### 2. BROADENING THE SCOPE OF THE ADAPTIVE THRESHOLDING ESTIMATOR

Let  $\tau_{\lambda}(\cdot)$  be a general thresholding function for which:

- (i)  $|\tau_{\lambda}(z)| \leq |y|$  for all *z* and *y* that satisfy  $|z y| \leq \lambda$ ;
- (ii)  $\tau_{\lambda}(z) = 0$  for  $|z| \leq \lambda$ ;
- (iii)  $|\tau_{\lambda}(z) z| \leq \lambda$  for all  $z \in \mathbb{R}$ .

Similar properties are set forth in Antoniadis & Fan (2001) and were proposed in the context of covariance estimation via thresholding in Rothman et al. (2009) and Cai & Liu (2011). Some examples of thresholding functions satisfying these three conditions are the soft thresholding rule  $\tau_{\lambda}(z) = \operatorname{sgn}(z)(z - \lambda)_+$ , the adaptive lasso rule  $\tau_{\lambda}(z) = z(1 - |\lambda/z|^{\eta})_+$  with  $\eta \ge 1$ , and the smoothly clipped absolute deviation thresholding rule (Rothman et al., 2009). Although the hard thresholding rule  $\tau_{\lambda}(z) = z \mathbb{1}(|z| > \lambda)$  does not satisfy (i), the results presented in this section also hold for hard thresholding. The adaptive thresholding estimator is defined as

$$\hat{\Sigma}^{\mathcal{T}} = (\hat{\sigma}_{uv}^{\mathcal{T}}) = \left\{ \tau_{\lambda_{uv}}(\hat{\sigma}_{uv}) \right\}$$

where  $\hat{\sigma}_{uv}$  is the (u, v)th entry of  $\hat{\Sigma}$  and the threshold  $\lambda_{uv}$  is entry-dependent. Equipped with these adaptive thresholds, Cai & Liu (2011) established optimal rates of convergence of the resulting estimator under sub-Gaussianity of X. To accommodate data drawn from distributions violating sub-Gaussianity, we replace the sample covariance matrix  $\hat{\Sigma}$  by a pilot estimator  $\tilde{\Sigma}$  satisfying (1). The resulting adaptive thresholding estimator is denoted by  $\tilde{\Sigma}^T$ . As suggested by Fan et al. (2013), the entry-dependent threshold

$$\lambda_{uv} = \lambda \left(\frac{\tilde{\sigma}_{uu}\tilde{\sigma}_{vv}\log p}{n}\right)^{1/2} \tag{3}$$

is used, where  $\lambda > 0$  is a constant. This is simpler than the threshold used by Cai & Liu (2011), as it does not require estimation of  $var(\tilde{\sigma}_{uv})$  and achieves the same optimality.

Let  $S^+(\mathbb{R}, p)$  denote the class of positive-definite symmetric matrices with elements in  $\mathbb{R}$ . Theorem 1 relies on the following conditions on the pilot estimator and the sparsity of  $\Sigma^*$ .

Condition 1. The pilot estimator  $\tilde{\Sigma} = (\tilde{\sigma}_{uv})$  satisfies (1).

*Condition* 2. The matrix  $\Sigma^* = (\sigma_{uv}^*)$  belongs to the class

$$\mathcal{U}_{q} = \mathcal{U}_{q}\{s_{0}(p)\} = \left\{ \Sigma : \Sigma \in \mathcal{S}^{+}(\mathbb{R}, p), \max_{u} \sum_{v=1}^{p} (\sigma_{uu}^{*} \sigma_{vv}^{*})^{(1-q)/2} |\sigma_{uv}^{*}|^{q} \leq s_{0}(p) \right\}.$$

The class of weakly sparse matrices  $U_q$  was introduced by Cai & Liu (2011). The columns of a covariance matrix in  $U_q$  are required to lie in a weighted  $\ell_q$ -ball, where the weights are determined by the variance of the entries of the population covariance.

THEOREM 1. Suppose that Conditions 1 and 2 hold,  $\log p = o(n)$ , and  $\min_u \sigma_{uu}^* = \gamma > 0$ . There exists a positive constant  $C_0$  such that

$$\inf_{\Sigma^* \in \mathcal{U}_q} \operatorname{pr}\left\{ \|\tilde{\Sigma}^{\mathcal{T}} - \Sigma^*\|_2 \leqslant C_0 s_0(p) \left(\frac{\log p}{n}\right)^{(1-q)/2} \right\} \ge 1 - \varepsilon_{n,p},$$

where  $\varepsilon_{n,p}$  is a deterministic sequence that decreases to zero as  $n, p \to \infty$ .

The constant  $C_0$  in Theorem 1 depends on q,  $\lambda$  and the unknown distribution of X, and so do the constants appearing in Theorem 2 and Propositions 2–4.

Our result generalizes Theorem 1 of Cai & Liu (2011); the minimax lower bound of our Theorem 1 matches theirs, implying that our procedure is minimax optimal for a wider class of distributions containing the sub-Gaussian distributions.

Cai & Liu (2011) also give convergence rates under bounded moments in all components of X. In that case, a much more stringent scaling condition on n and p is required, as shown in Theorem 1(ii) of Cai & Liu (2011). Their result does not cover the high-dimensional case where p > n when fewer than  $8 + \varepsilon$  finite moments exist. If a larger number of finite moments is assumed, p is allowed to increase polynomially with n. However, we allow  $\log p = o(n)$ .

For the three pilot estimators to be given in 4, even universal thresholding can achieve the same minimax optimal rate given the bounded fourth moments assumed there. However, adaptive thresholding as formulated in (3) results in better numerical performance.

Unfortunately,  $\tilde{\Sigma}^{\mathcal{T}}$  may not be positive semidefinite, but it can be projected onto the cone of positive-semidefinite matrices through the convex optimization

$$\tilde{\Sigma}_{+}^{\mathcal{T}} = \underset{\Sigma \succeq 0}{\operatorname{arg\,min}} \|\Sigma - \tilde{\Sigma}^{\mathcal{T}}\|_{2}.$$
(4)

By definition,  $\|\tilde{\Sigma}_{+}^{\mathcal{T}} - \tilde{\Sigma}^{\mathcal{T}}\|_{2} \leqslant \|\Sigma^{*} - \tilde{\Sigma}^{\mathcal{T}}\|_{2}$ , so the triangle inequality yields

$$\|\tilde{\Sigma}_{+}^{\mathcal{T}} - \Sigma^{*}\|_{2} \leqslant \|\tilde{\Sigma}_{+}^{\mathcal{T}} - \tilde{\Sigma}^{\mathcal{T}}\|_{2} + \|\tilde{\Sigma}^{\mathcal{T}} - \Sigma^{*}\|_{2} \leqslant 2 \, \|\tilde{\Sigma}^{\mathcal{T}} - \Sigma^{*}\|_{2}.$$

Hence, the price to pay for projection is no more than a factor of two, which does not affect the convergence rate. The projection is easily made by linear programming (Boyd & Vandenberghe, 2004).

## 3. Broadening the scope of the adaptively constrained $\ell_1\text{-minimization}$ estimator

We consider a robust modification of the adaptively constrained  $\ell_1$ -minimization estimator of Cai et al. (2016). In a spirit similar to § 2, our robust modification relies on the existence of a pilot estimator  $\tilde{\Sigma}$  satisfying (2). Construction of the robust adaptive constrained  $\ell_1$ -minimizer relies on a preliminary projection, resulting in the positive-definite estimator

$$\tilde{\Sigma}^{+} = \underset{\Sigma \succeq \varepsilon I_{p}}{\operatorname{arg\,min}} \|\Sigma - \tilde{\Sigma}\|_{\max}$$
(5)

for an arbitrarily small positive number  $\varepsilon$ . The minimization problem in (5) can be rewritten as minimizing  $\vartheta$  such that  $|(\tilde{\Sigma} - \Sigma)_{uv}| \leq \vartheta$  and  $\Sigma \succeq \varepsilon I_p$  for all  $1 \leq u, v \leq p$ . This problem can be solved in Matlab using the cvx solver (Grant & Boyd, 2014).

Given  $\tilde{\Sigma}^+ = (\tilde{\sigma}_{uv}^+)$ , our estimator of  $\Omega^*$  is constructed by replacing  $(\hat{\Sigma} + n^{-1}I_p)$  with  $\tilde{\Sigma}^+$  in the original constrained  $\ell_1$ -minimization procedure. For ease of reference, the steps are reproduced below. Define the first-stage estimator  $\check{\Omega}^{(1)}$  of  $\Omega^*$  through the vectors

$$\check{\omega}_{\nu}^{\dagger} = \operatorname*{arg\,min}_{\omega_{\nu} \in \mathbb{R}^{p}} \left\{ \|\omega_{\nu}\|_{1} : \|\tilde{\Sigma}^{+}\omega_{\nu} - e_{\nu}\|_{\infty} \leqslant \delta_{n,p} \max_{\nu} (\tilde{\sigma}_{\nu\nu}^{+}) \, \omega_{\nu\nu}, \, \omega_{\nu\nu} > 0 \right\}, \quad \nu \in [p], \quad (6)$$

with  $\omega_v = (\omega_{1v}, \dots, \omega_{pv})^T$ ,  $\delta_{n,p} = \delta\{(\log p)/n\}^{1/2}$  for  $\delta > 0$ , and  $e_v$  being the vector that has value 1 in the vth coordinate and zeros elsewhere. More specifically, define  $\check{\omega}_v^{(1)}$  as an adjustment of  $\check{\omega}_v^{\dagger}$  such that the vth entry is

$$\check{\omega}_{vv}^{(1)} = \check{\omega}_{vv}^{\dagger} \,\mathbb{1}\left\{\tilde{\sigma}_{vv}^{+} \leqslant (n/\log p)^{1/2}\right\} + \{(\log p)/n\}^{1/2} \,\mathbb{1}\left\{\tilde{\sigma}_{vv}^{+} > (n/\log p)^{1/2}\right\},\tag{7}$$

and define the first-stage estimator as  $\check{\Omega}^{(1)} = (\check{\omega}_1^{(1)}, \dots, \check{\omega}_p^{(1)})$ . A second-stage adaptive estimator  $\check{\Omega}^{(2)} = (\check{\omega}_1^{(2)}, \dots, \check{\omega}_p^{(2)})$  is defined by solving, for each column,

$$\check{\omega}_{\nu}^{(2)} = \operatorname*{arg\,min}_{\omega_{\nu} \in \mathbb{R}^{p}} \left\{ \|\omega_{\nu}\|_{1} : \left| \left( \tilde{\Sigma}^{+} \omega_{\nu} - e_{\nu} \right)_{u} \right| \leqslant \lambda_{n,p} (\tilde{\sigma}_{uu}^{+} \check{\omega}_{\nu\nu}^{(1)})^{1/2} \ (u = 1, \dots, p) \right\}, \tag{8}$$

where  $\lambda_{n,p} = \lambda \{(\log p)/n\}^{1/2}$  for  $\lambda > 0$ . In practice, the optimal values of  $\delta$  and  $\lambda$  are chosen by crossvalidation. The final estimator,  $\tilde{\Omega}$ , of  $\Omega^*$  is a symmetrized version of  $\check{\Omega}^{(2)}$  constructed as

$$\tilde{\Omega} = (\tilde{\omega}_{uv}), \quad \tilde{\omega}_{uv} = \tilde{\omega}_{vu} = \check{\omega}_{uv}^{(2)} \,\mathbbm{1}(|\check{\omega}_{uv}^{(2)}| \leqslant |\check{\omega}_{vu}^{(2)}|) + \check{\omega}_{vu}^{(2)} \,\mathbbm{1}(|\check{\omega}_{uv}^{(2)}| > |\check{\omega}_{vu}^{(2)}|). \tag{9}$$

The theoretical properties of  $\tilde{\Omega}$  are derived under Conditions 3 and 4.

Condition 3. The pilot estimator  $\tilde{\Sigma} = (\tilde{\sigma}_{uv})$  satisfies (2).

Condition 4. The matrix  $\Omega^* = (\omega_{uv}^*)$  belongs to the class

$$\mathcal{G}_{q} = \mathcal{G}_{q}(c_{n,p}, M_{n,p}) = \left\{ \Omega \in \mathcal{S}^{+}(\mathbb{R}, p) : \max_{v} \sum_{u=1}^{p} |\omega_{uv}|^{q} \leqslant c_{n,p}, \|\Omega\|_{1} \leqslant M_{n,p}, \\ \frac{1}{M_{1}} \leqslant \lambda_{\min}(\Omega) \leqslant \lambda_{\max}(\Omega) \leqslant M_{1} \right\},$$

where  $0 \le q \le 1$ ,  $M_1 > 0$  is a constant, and  $M_{n,p}$  and  $c_{n,p}$  are positive deterministic sequences that are bounded away from zero and allowed to diverge as *n* and *p* grow.

In this class of precision matrices, sparsity is imposed by restricting the columns of  $\Omega^*$  to lie in an  $\ell_q$ -ball of radius  $c_{n,p}$  ( $0 \le q < 1$ ).

THEOREM 2. Suppose that Conditions 1, 3 and 4 are satisfied with  $c_{n,p} = o(n/\log p)$ . Under the scaling condition  $\log p = O(n^{1/2})$  we have, for a positive constant  $C_0$ ,

$$\inf_{\Omega^*\in\mathcal{G}_q} \Pr\left\{\|\tilde{\Omega}-\Omega^*\|_2 \leqslant C_0 M_{n,p}^{1-q} c_{n,p} \left(\frac{\log p}{n}\right)^{(1-q)/2}\right\} \geqslant 1-\varepsilon_{n,p},$$

where  $\varepsilon_{n,p}$  is a deterministic sequence that decreases to zero as  $n, p \to \infty$  and  $\tilde{\Omega}$  is the robust adaptively constrained  $\ell_1$ -minimization estimator described in (6)–(9).

*Remark* 1. Our class of precision matrices is slightly more restrictive than that considered in Cai et al. (2016), since we require  $1/M_1 \leq \lambda_{\min}(\Omega^*) \leq \lambda_{\max}(\Omega^*) \leq M_1$  instead of  $\lambda_{\max}(\Omega^*)/\lambda_{\min}(\Omega^*) \leq M_1$ . The difference is marginal since  $\sigma_{uu}^* = e_u^T \Sigma^* e_u = \|\Sigma^{*1/2} e_u\|_2^2 \leq \lambda_{\max}(\Sigma^*) = 1/\lambda_{\min}(\Omega^*)$  and  $\lambda_{\max}(\Omega^*)/\lambda_{\min}(\Omega^*) \leq M_1$  implies that  $0 < M_1^{-1}\lambda_{\max}(\Omega^*) \leq \lambda_{\min}(\Omega^*) \leq \lambda_{\min}(\Omega^*) \leq \infty$ . We therefore only exclude precision matrices associated with either exploding or imploding covariance matrices, i.e., we exclude  $\sigma_{uu}^* \to 0$  and  $\sigma_{uu}^* \to \infty$  for all  $u \in [p]$ . Ren et al. (2015) also require  $1/M_1 \leq \lambda_{\min}(\Omega^*) \leq \lambda_{\max}(\Omega^*) \leq M_1$ .

A positive-semidefinite estimator with the same convergence rate as  $\tilde{\Omega}$  can be constructed by projecting the symmetric matrix  $\tilde{\Omega}$  onto the cone of positive-semidefinite matrices, as in (4).

Next, we present three pilot estimators whose performance is favourable with respect to the sample covariance matrix when the sub-Gaussianity assumption is violated. We verify Conditions 1 and 3 for these estimators. Condition 1 will be verified for all three pilot estimators. When  $\|\Omega^*\|_1$  is bounded, Condition 1 implies Condition 3 because  $\|\tilde{\Sigma}\Omega^* - I_p\|_{max} = \|(\tilde{\Sigma} - \Sigma^*)\Omega^*\|_{max} \le \|\Omega^*\|_1 \|\tilde{\Sigma} - \Sigma^*\|_{max}$ . When  $\|\Omega^*\|_1 \to \infty$ , Condition 3 is verified for the adaptive Huber estimator. We emphasize that Condition 3 is only needed if the goal is to obtain a minimax optimal estimator of  $\Omega$ . A consistent estimator is still attainable if only Condition 1 holds when  $\|\Omega^*\|_1 \to \infty$ . A more thorough discussion appears in the Supplementary Material.

#### 4. ROBUST PILOT ESTIMATORS

#### 4.1. A rank-based estimator

The rank-based estimator requires only the existence of the second moment. However, it makes arguably more restrictive assumptions, as it requires the distribution of X to be elliptically symmetric.

DEFINITION 1. A random vector  $Z = (Z_1, ..., Z_p)^T$  follows an elliptically symmetric distribution if and only if  $Z = \mu + \xi AU$ , where  $\mu \in \mathbb{R}^p$ ,  $A \in \mathbb{R}^{d \times q}$  with  $q = \operatorname{rank}(A)$ , U is uniformly distributed on the unit sphere in  $\mathbb{R}^q$ , and  $\xi$  is a positive random variable independent of U.

Observe that  $\Sigma^* = D^* R^* D^*$  where  $R = (r_{uv}^*)$  denotes the correlation matrix and  $D^* = \text{diag}\{(\sigma_{11}^*)^{1/2}, \dots, (\sigma_{pp}^*)^{1/2}\}$ . Liu et al. (2012) and Xue & Zou (2012) both proposed rank-based estimation of  $R^*$ , exploiting a bijective mapping between Pearson correlation and Kendall's tau or Spearman's rho dependence measures that hold for elliptical distributions. More specifically, Kendall's tau concordance between  $X_u$  and  $X_v$  is defined as

$$\tau_{uv}^* = \Pr\{(X_u - Y_u)(X_v - Y_v) > 0\} - \Pr\{(X_u - Y_u)(X_v - Y_v) < 0\},\$$

where Y is an independent copy of X. With  $X_i = (X_{i,1}, \ldots, X_{i,p})^T$ , the empirical analogue of  $\tau_{uv}^*$  is

$$\tilde{\tau}_{uv} = \binom{n}{2}^{-1} \sum_{i} \sum_{j < i} \left[ \mathbb{1}\left\{ (X_{iu} - Y_{iu})(X_{iv} - Y_{iv}) > 0 \right\} - \mathbb{1}\left\{ (X_{iu} - Y_{iu})(X_{iv} - Y_{iv}) < 0 \right\} \right].$$

Since  $\tau_{uv}^* = 2\pi^{-1} \arcsin(r_{uv}^*)$ , an estimator of  $R^*$  is  $\tilde{R} = (\tilde{r}_{uv}) = \{\sin(\pi \tilde{\tau}_{uv}/2)\}$ . An analogous bijection exists between Spearman's rho and Pearson's correlation; see Xue & Zou (2012) for details. We propose to estimate the elements of the diagonal matrix  $D^*$  using a median absolute deviation estimator,  $\tilde{D} = \text{diag}\{(\tilde{\sigma}_{11})^{1/2}, \ldots, (\tilde{\sigma}_{pp})^{1/2}\}$ , where  $\tilde{\sigma}_{uu} = C_u \text{med}_{i \in [n]}\{|X_{iu} - \text{med}_{j \in [n]}(X_{ju})|\}$ . Here,  $\text{med}_{i \in [n]}(\cdot)$  denotes the median within the index set [n] and  $C_u = F_u^{-1}(3/4)$  is the Fisher consistency constant, where  $F_u$  is the distribution function of  $X_{1u} - \nu_u$  and  $\nu_u$  is the median of  $X_{1u}$ . Finally, the rank-based estimator is defined as  $\tilde{\Sigma}_R = (\tilde{\sigma}_{uv}^R) = \tilde{D}\tilde{R}\tilde{D}$ .

PROPOSITION 2. Let  $X_1, \ldots, X_n$  be independent and identically distributed copies of the elliptically symmetric random vector X with covariance matrix  $\Sigma^* = D^*R^*D^*$ . Assume that  $\max_u \sigma_{uu}^* = \varsigma < \infty$  and  $\min_u \sigma_{uu}^* > C_2\{(\log p)/n\}^{1/2} + 1/U^4$ , where  $U < C_1\pi \sqrt{2}/(4\varsigma)$  for  $C_1 > 0$  and  $C_2 > 0$ . Then

$$\Pr\left[\max_{u,v} |\tilde{\sigma}_{uv}^{R} - \sigma_{uv}^{*}| \leq c \{(\log p)/n\}^{1/2}\right] \ge 1 - \varepsilon_{n,p}$$

with  $\varepsilon_{n,p} \leq C_0 p^{-L}$  for positive constants c,  $C_0$  and L.

In estimating marginal variances, we use median absolute deviation estimators to avoid higher moment assumptions. This assumes knowledge of  $F_u^{-1}(3/4)$ , without which these marginal variances can be estimated by using the adaptive Huber estimator or the median of means estimator given in the next two subsections. This requires existence of a fourth moment; see Propositions 3 and 5.

#### 4.2. An adaptive Huber estimator

The Huber-type M-estimator only requires the existence of fourth moments. Let  $Y_{uv} = (X_u - \mu_u^*)(X_v - \mu_v^*)$ . Then  $\sigma_{uv}^* = E(Y_{uv}) = \mu_{uv}^* - \mu_u^* \mu_v^*$  where  $\mu_u^* = E(X_u)$ ,  $\mu_v^* = E(X_v)$  and  $\mu_{uv}^* = E(X_uX_v)$ . We propose to estimate  $\sigma_{uv}^*$  robustly through robust estimators of  $\mu_u^*$ ,  $\mu_v^*$  and  $\mu_{uv}^*$ . For independent and identically distributed copies  $Z_1, \ldots, Z_n$  of a real random variable Z with mean  $\mu$ , Huber's (1964) M-estimator of  $\mu$  is defined as the solution to

$$\sum_{i=1}^{n} \psi_H(Z_i - \mu) = 0, \tag{10}$$

where  $\psi_H(z) = \min\{H, \max(-H, z)\}$  is the Huber function. Replacing  $Z_i$  in (10) by  $X_{i,u}, X_{i,u}$ and  $X_{i,u}X_{i,v}$  gives the Huber estimators  $\tilde{\mu}_u^H, \tilde{\mu}_v^H$  and  $\tilde{\mu}_{uv}^H$  of  $\mu_u^*, \mu_v^*$  and  $\mu_{uv}^*$ , respectively, from which the Huber-type estimator of  $\Sigma^*$  is defined as  $\tilde{\Sigma}_H = (\tilde{\sigma}_{uv}^H) = (\tilde{\mu}_{uv}^H - \tilde{\mu}_u^H \tilde{\mu}_v^H)$ .

We depart from Huber (1964) by allowing H to grow to infinity as n increases, as our objectives differ from those of Huber (1964) and of classical robust statistics (Huber & Ronchetti, 2009). There, the distribution generating the data is assumed to be a contaminated version of a given parametric model, where the contamination level is small, and the objective is to estimate features of the parametric model as if no contamination were present. Our goal is instead to estimate the mean of the underlying distribution, allowing departures from sub-Gaussianity. In related work, Fan et al. (2017) have shown that when H is allowed to diverge at an appropriate rate, the Huber estimator of the mean concentrates exponentially fast around the true mean when only a finite second moment exists. In a similar spirit, we allow H to grow with n in order to alleviate the bias. An appropriate choice of H trades off bias and robustness. We build on Fan et al. (2017) and Catoni (2012), showing that our proposed Huber-type estimator satisfies Conditions 1 and 3.

PROPOSITION 3. Assume  $\max_{1 \le u \le p} E(X_u^4) = \kappa^2 < \infty$ . Let  $\tilde{\Sigma}_H = (\tilde{\sigma}_{uv}^H)$  be the Huber-type estimator with  $H = K(n/\log p)^{1/2}$  for  $K \ge 4\kappa (2+L)^{1/2}$  and L > 0 satisfying  $(2+L)(\log p)/n < 1/8$ . Under the scaling condition  $(\log p)/n \to 0$  we have, for large n and a constant  $C > \kappa(1+2\max_u |\mu_u^*|)$ ,

$$\Pr\left[\max_{u,v} |\tilde{\sigma}_{uv}^H - \sigma_{uv}^*| \leqslant C\{(\log p)/n\}^{1/2}\right] \geqslant 1 - \varepsilon_{n,p},$$

where  $\varepsilon_{n,p} \leq C_0 p^{-L}$  for positive constants  $C_0$  and L.

Proposition 3 verifies Condition 1 for  $\tilde{\Sigma}_H$ , provided H is chosen to diverge at the appropriate rate. As quantified in Proposition 4,  $\tilde{\Sigma}_H$  also satisfies Condition 3 when H is of the same rate as in Proposition 3. The proof of this result entails extending a large deviation result of Petrov (1995).

PROPOSITION 4. Assume that  $\max_{1 \le u \le p} E(X_u^4) = \kappa^2 < \infty$  and  $\Omega^* \in \mathcal{G}_q(c_{n,p}, M_{n,p})$  with  $c_{n,p} = O\{n^{(1-q)/2}/(\log p)^{(3-q)/2}\}$ . Let  $\tilde{\Sigma}_H = (\tilde{\sigma}_{uv}^H)$  be the Huber-type estimator defined below (10) with  $H = K(n/\log p)^{1/2}$  for  $K \ge 4\kappa(2+L)^{1/2}$  and L > 0. Assume that the truncated population covariance matrix  $\Sigma_H = E\{\mathbb{1}(|X_uX_v| \le H)X_uX_v\}$  satisfies  $\|\Sigma_H\Omega^* - I_p\|_{\max} = O[\{(\log p)/n\}^{1/2}]$ . Under the scaling condition  $(\log p)/n^{1/3} = O(1)$  we have, for large n and a constant  $C > \kappa(1+2\max_u |\mu_u^*|)$ ,

$$\Pr\left[\max_{u,v} \left| (\tilde{\Sigma}_H \Omega^* - I_p)_{uv} \right| \leq C \{ (\log p)/n \}^{1/2} \right] \geq 1 - \varepsilon_{n,p},$$

where  $\varepsilon_{n,p} \leq C_0 (\log p)^{-1/2} p^{-L}$  for positive constants  $C_0$  and L.

#### 4.3. A median of means estimator

The median of means estimator was proposed by Nemirovsky & Yudin (1983) and has been further studied by Lerasle & Oliveira (2011), Bubeck et al. (2013) and Joly & Lugosi (2016). It is defined as the median of M means obtained by partitioning the data into M subsamples. A heuristic explanation for its success is that taking means within subsamples results in a more symmetric sample while the median makes the solution concentrate faster.

Our median of means estimator for  $\Sigma^*$  is constructed as  $\tilde{\Sigma}_M = (\tilde{\sigma}_{uv}^M) = (\tilde{\mu}_{uv}^M - \tilde{\mu}_u^M \tilde{\mu}_v^M)$ , where  $\tilde{\mu}_{uv}^M$ ,  $\tilde{\mu}_u^M$  and  $\tilde{\mu}_v^M$  are median of means estimators of  $(X_{iu}X_{iv})_{i=1}^n$ ,  $(X_{iu})_{i=1}^n$  and  $(X_{iv})_{i=1}^n$ , respectively; in each case, each of the *M* means is computed on an regular partition  $B_1, \ldots, B_M$ of [*n*]. It is assumed that *M* is a factor of *n*.

The value of M is a tuning parameter that affects the accuracy of the median of means estimator. The choice of M involves a compromise between bias and variance. For the extreme cases, M = n and M = 1, we obtain respectively the sample median and the sample mean. The latter is asymptotically unbiased but does not concentrate exponentially fast in the presence of heavy tails, while the former concentrates exponentially fast but not to the population mean under asymmetric distributions. Proposition 5 gives the range of M for which both goals are achieved simultaneously.

PROPOSITION 5. Assume  $\max_{1 \le u \le p} E(X_u^4) = \kappa^2 < \infty$ . Let  $\tilde{\Sigma}_M = (\tilde{\sigma}_{uv}^M)$  be the median of means estimator described above based on a regular partition  $B_1, \ldots, B_M$  with  $M = \lceil (2+L) \log p \rceil$  for a positive constant L. Under the scaling condition  $(\log p)/n \to 0$  we have, for large n and a constant  $C > 2(6e)^{1/2} \{\kappa + 2 \max_{u,v} \mu_u^*(\sigma_{vv}^*)^{1/2}\}$ ,

$$\Pr\left[\max_{u,v} |\tilde{\sigma}_{uv}^M - \sigma_{uv}^*| \leqslant C\{(\log p)/n\}^{1/2}\right] \ge 1 - \varepsilon_{n,p},$$

where  $\varepsilon_{n,p} \leq C_0 p^{-L}$  for positive constants  $C_0$  and L.

#### 5. INFINITE KURTOSIS

In the previous discussion we assumed the existence of fourth moments of X for the Hubertype estimator in § 4. We now relax the condition of boundedness of  $E(X_u^4)$  to that of  $E(|X_u|^{2+\varepsilon})$ for some  $\varepsilon > 0$  and all  $u \in [p]$ . The following proposition lays the foundations for the analysis of high-dimensional covariance or precision matrix estimation with infinite kurtosis. It extends Theorem 5 in Fan et al. (2017) and gives rates of convergence for Huber's estimator of  $E(X_u)$ assuming a bounded  $1 + \varepsilon$  moment for  $\varepsilon \in (0, 1]$ . The result is optimal in the sense that our rates match the minimax lower bound given in Theorem 3.1 of Devroye et al. (2016). The rates depend on  $\varepsilon$ , and when  $\varepsilon = 1$  they match those of Catoni (2012) and Fan et al. (2017).

PROPOSITION 6. Let  $\delta \in (0, 1)$ ,  $\varepsilon \in (0, 1]$  and  $n > 12 \log(2\delta^{-1})$ , and let  $Z_1, \ldots, Z_n$  be independent and identically distributed random variables with mean  $\mu$  and bounded  $1 + \varepsilon$  moment, i.e.,  $E(|Z_1 - \mu|^{1+\varepsilon}) = v < \infty$ . Take  $H = \{vn/\log(2\delta^{-1})\}^{1/(1+\varepsilon)}$ . Then, with probability at least  $1 - \delta$ ,

$$ilde{\mu}^H - \mu \leqslant rac{7+\sqrt{2}}{2} \, v^{1/(1+arepsilon)} \left\{ rac{\log(2\delta^{-1})}{n} 
ight\}^{arepsilon/(1+arepsilon)},$$

where  $\tilde{\mu}^H$  is as defined in § 4.2.

COROLLARY 1. Under the conditions of Proposition 6, the Huber estimator satisfies

$$\Pr\left[|\tilde{\mu}^H - \mu| \leqslant \frac{7 + \sqrt{2}}{2} v^{1/(1+\varepsilon)} \left\{\frac{\log(2\delta^{-1})}{n}\right\}^{\varepsilon/(1+\varepsilon)}\right] \geqslant 1 - 2\delta.$$

Corollary 1 allows us to generalize the upper bounds of the Huber-type estimator. The following two theorems establish rates of convergence for the adaptive thresholding and the adaptively constrained  $\ell_1$ -minimization estimators. While we do not prove that these rates are minimax optimal under  $2 + \varepsilon$  finite moments, the proof expands on the elementwise maximum norm convergence of the pilot estimator, which is optimal by Theorem 3.1 of Devroye et al. (2016), and the resulting rates for adaptive thresholding match the minimax rates of Cai & Liu (2011) when  $\varepsilon = 2$ . This is a strong indication that the rates are sharp.

THEOREM 3. Suppose that Condition 2 is satisfied and assume  $\max_{1 \le u \le p} E(|X_u|^{2+\varepsilon}) \le \kappa_{\varepsilon}^2$ . Let  $\hat{\Sigma}_H^T$  be the adaptive thresholding estimator defined in § 2 based on the Huber pilot estimator  $\tilde{\Sigma}_H$  with  $H = K(n/\log p)^{1/(2+\varepsilon)}$  for  $K \ge 2^{-1}(7 + \sqrt{2})\kappa_{\varepsilon}(2 + L)^{\varepsilon/(2+\varepsilon)}$  and L > 0. Under the scaling condition  $\log p = O(n^{1/2})$  and choosing  $\lambda_{uv} = \lambda \{\tilde{\sigma}_{uu}^H \tilde{\sigma}_{vv}^H (\log p)/n\}^{\varepsilon/(2+\varepsilon)}$  for some  $\lambda > 0$ , we have, for sufficiently large n,

$$\inf_{\Sigma^* \in \mathcal{U}_q} \Pr\left\{ \| \hat{\Sigma}_H^{\mathcal{T}} - \Sigma^* \|_2 \leqslant Cs_0(p) \left( \frac{\log p}{n} \right)^{\varepsilon(1-q)/(2+\varepsilon)} \right\} \ge 1 - \varepsilon_{n,p}$$

where  $\varepsilon_{n,p} \leq C_0 p^{-L}$  for positive constants  $C_0$  and L.

THEOREM 4. Suppose that Condition 4 is satisfied,  $\max_{1 \le u \le p} E(|X_u|^{2+\varepsilon}) \le \kappa_{\varepsilon}^2$  and  $c_{n,p} = O\{n^{(1-q)/2}/(\log p)^{(3-q)/2}\}$ . Let  $\hat{\Omega}_H$  be the adaptively constrained  $\ell_1$ -minimization estimator defined in § 3 based on the Huber pilot estimator  $\tilde{\Sigma}_H$  with  $H = K(n/\log p)^{1/(2+\varepsilon)}$  for  $K \ge 2^{-1}(7+\sqrt{2})\kappa_{\varepsilon}(2+L)^{\varepsilon/(2+\varepsilon)}$  and L > 0. Assume that the truncated population covariance matrix  $\Sigma_H = E\{\mathbb{1}(|X_uX_v| \le H)X_uX_v\}$  satisfies  $\|\Sigma_H \Omega^* - I_p\|_{\max} = O[\{(\log p)/n\}^{\varepsilon/(2+\varepsilon)}]$ . Under the scaling condition  $(\log p)/n^{1/3} = O(1)$ , we have, for sufficiently large n,

$$\inf_{\Omega^* \in \mathcal{G}_q} \Pr\left\{ \|\tilde{\Omega}_H - \Omega^*\|_2 \leqslant C M_{n,p}^{1-q} c_{n,p} \left(\frac{\log p}{n}\right)^{\varepsilon(1-q)/(2+\varepsilon)} \right\} \ge 1 - \varepsilon_{n,p},$$

where  $\varepsilon_{n,p} \leq C_0 p^{-L}$  for positive constants  $C_0$  and L.

A result similar to Proposition 6 was obtained in Lemma 2 of Bubeck et al. (2013) for the median of means estimator. Expanding on it, we obtain a result analogous to Theorem 3 for the median of means matrix estimator.

#### 6. FINITE-SAMPLE PERFORMANCE

We illustrate the performance of the estimators discussed in § § 2 and 3 under a range of datagenerating scenarios and for every choice of pilot estimator discussed in § 4. For the adaptive

Table 1. Estimation errors (with standard errors in parentheses) of the adaptive thresholding estimator of  $\Sigma^*$  based on four different pilot estimators; values are averaged over 500 replications

MVN, the normal distribution; T, the t distribution; ST, the skewed t distribution; CST, the contaminated skewed t distribution.

thresholding estimator of  $\Sigma^*$ , we use a hard thresholding rule with the entry-dependent thresholds of (3). In each of 500 Monte Carlo replications, n = 200 independent copies of a random vector X of dimension p = 400 are drawn from a model with either a sparse covariance matrix  $\Sigma^*$  or a sparse precision matrix  $\Omega^*$ , depending on the experiment. We consider four different scenarios for the distribution of X: the zero-mean multivariate normal distribution; the t distribution with 3.5 degrees of freedom and infinite kurtosis; the skewed t distribution with four degrees of freedom and skew parameter equal to 20; and the contaminated skewed t distribution (Azzalini, 2005) with four degrees of freedom and skew parameter equal to 10. Data in the last scenario are generated as  $X = (1 - b)Z_1 + bZ_2$ , where  $Z_1 \sim P$ ,  $Z_2 \sim Q$  and  $b \sim Bi(1, 0.05)$ ; here P is the t distribution generating most of the data, while Q is a normal distribution with a mean vector of -8 and covariance matrix equal to the identity. Any unspecified tuning parameters from the adaptive thresholding estimator and adaptively constrained  $\ell_1$ -minimization estimator are chosen by crossvalidation to minimize the spectral norm error. Unspecified constants in the tuning parameters of the robust pilot estimators are conservatively chosen to be those that would be optimal if the true distribution was a Student t distribution with five degrees of freedom. We consider the following two structures for  $\Sigma^*$  and  $\Omega^*$ .

- (i) Sparse covariance matrix: similar to Model 2 in the simulation section of Cai & Liu (2011), we take the true covariance model to be the block-diagonal matrix Σ\* = blockdiag(Σ<sub>1</sub><sup>\*</sup>, Σ<sub>2</sub><sup>\*</sup>), where Σ<sub>2</sub><sup>\*</sup> = 4I<sub>p/2×p/2</sub>, Σ<sub>1</sub><sup>\*</sup> = A + εI<sub>p/2×p/2</sub>, A = (a<sub>uv</sub>) with independent a<sub>uv</sub> = Un(0·3, 0·8) × Bi(1, 0·2) and ε = max{-λ<sub>min</sub>(A), 0} + 0·01 to ensure that Σ<sub>1</sub><sup>\*</sup> is positive definite.
- (ii) Banded precision matrix: following Cai et al. (2016), we take the true precision matrix to be of the banded form  $\Omega_0 = \{\omega_{ij}\}$ , where  $\omega_{ii} = 1$ ,  $\omega_{i,i+1} = 0.6$ ,  $\omega_{i+2,i} = \omega_{i,i+2} = 0.3$  and  $\omega_{ij} = 0$  for  $|i j| \ge 3$ .

Table 1 shows that while the sample covariance estimator performs well for the normally distributed case, when the true model departs from normality, thresholding this estimator gives poor performance, reflected by its elevated estimation error in both the maximum norm and the spectral norm. By contrast, thresholding one of our proposed robust pilot estimators does not suffer from these heavy-tailed distributions. Table 2 shows a similar pattern for the precision matrix estimators. The gains are apparent for all robust pilot estimators, as predicted by our theory.

#### 7. Real-data example

A gene regulatory network, also known as a pathway, is a set of genes that interact with each other to control a specific cell function. With recent advances in genomic research, many such networks have been discovered and their functions thoroughly studied. Certain pathways are now known and available in public databases such as KEGG (Ogata et al., 2000). One popular way to infer a gene regulatory network is through estimation of the precision matrix associated with gene expression (Wit & Abbruzzo, 2015). However, such data often contain outliers. To assess whether our robust estimator can improve inference on gene regulatory networks, we use a microarray dataset and compare our findings with generally acknowledged scientific truth from the genomics literature. The microarray data come from a study by Huang et al. (2011) on the inflammation process of cardiovascular disease. They identified that the toll-like receptor signalling pathway plays a key role in the inflammation process. Their study involves n = 48 patients and the data are available from the Gene Expression Omnibus via the accession name GSE20129. We consider 95 genes from the toll-like receptor signalling pathway and another 62 genes from the peroxisome proliferator-activated receptor signalling pathway, which is known to be unrelated to cardiovascular disease. A good method should discover connections for genes within each of the pathways but not across them. We use both the original version of the adaptively constrained  $\ell_1$ -minimization estimator and our robustified version via the Huber pilot estimator to estimate the precision matrix and therefore the gene regulatory network.

We first choose the tuning parameters that deliver the top 100 connections for each method. Table 3 reports the selection results, also displayed in Fig. 1. Our robust method identifies more connections within each pathway and fewer connections across the pathways.

We tried taking the same tuning parameter in the constrained  $\ell_1$ -minimization step (8) for each procedure. Table 3 gives the results. Our estimator detects fewer connections; however, the percentage of within-pathway connections estimated using the Huber pilot estimator is much higher than that of the sample covariance estimator. If the genomics literature is correct, our

Fig. 1. Connections estimated by the adaptively constrained  $\ell_1$ -minimization estimator using (a) the sample covariance and (b) the Huber-type pilot estimator; blue lines represent within-pathway connections and red lines between-pathway connections.

results show that use of the Huber pilot estimator improves inference for this example, in which heavy tails and skewness are present.

#### SUMMARY

This supplementary file contains proofs of the theoretical results in the main paper, complementary discussions of different technical aspects of our theory, and an additional plot for our real-data example.

#### S1. PROOFS

*Proof of Proposition* 1. We adapt the arguments of Lemma 3 in Bubeck et al. (2013) to our setting. Without loss of generality, we assume E(X) = 0 and construct the distribution pr as

$$\operatorname{pr}(X_{1u}X_{1v} = 0) = 1 - \alpha^{1+\gamma}, \quad \operatorname{pr}(X_{1u}X_{1v} = 1/\alpha) = \alpha^{1+\gamma}$$

for some  $\alpha \in (0, 1)$ . It is easy to check that  $\sigma_{uv}^* = E(X_u X_v) = \alpha^{\gamma}$  and  $E(|X_u X_v - \sigma_{uv}^*|^{1+\gamma}) \leq 2$ . Let  $\eta = 2^{-1} \varepsilon^{-1/(1+\gamma)} n^{-\gamma/(1+\gamma)}$  and take  $\alpha = (2n\eta)^{-1}$ . If  $\varepsilon < 1/2$ , we have  $\sigma_{uv}^* = \alpha^{\gamma} = 1$ 

5

10

 $(2n\eta)^{-\gamma} < \eta$ , which implies  $1/\alpha = 2n\eta > n(\eta + \sigma_{uv}^*)$ . This leads to the bound

$$pr(|\hat{\sigma}_{uv} - \sigma_{uv}^*| > \eta) \ge pr\{\hat{\sigma}_{uv} - \sigma_{uv}^* > \eta\}$$
  

$$\geqslant pr(\exists i \in [n] : X_{iu}X_{iv} > n(\eta + \sigma_{uv}^*))$$
  

$$\geqslant pr(\exists i \in [n] : X_{iu}X_{iv} = 1/\alpha)$$
  

$$= 1 - (1 - \alpha^{1+\gamma})^n$$
  

$$= 1 - \exp\left[n\log\left\{1 - \frac{1}{(2n\eta)^{1+\gamma}}\right\}\right]$$
  

$$\geqslant 1 - \exp\left\{-\frac{1}{n^{\gamma}(2\eta)^{1+\gamma}}\right\}$$
  

$$\geqslant \frac{1}{n^{\gamma}(2\eta)^{1+\gamma}}$$
  

$$= \varepsilon.$$

Proof of Theorem 1. Once the critical condition (1) is satisfied by the pilot estimator, the proof follows similar arguments as in the proof of Theorem 1 in Rothman et al. (2009) and the proof of Theorem 2 in Cai & Liu (2011). For ease of reference, the complete argument is given here.

Consider the event  $\mathcal{E}_n = \mathsf{E}_1 \cap \mathsf{E}_2 = \{ |\tilde{\sigma}_{uv} - \sigma_{uv}^*| \leq \lambda_{uv} \text{ for all } u, v \} \cap \{ \tilde{\sigma}_{uu} \tilde{\sigma}_{vv} \leq 2\sigma_{uu}^* \sigma_{vv}^* \text{ for all } u, v \}$ . We first show that on the event  $\mathcal{E}_n$ ,  $||\hat{\Sigma}^T - \Sigma^*||_2 \leq C_0 s_0(p) \{ (\log p)/n \}^{(1-q)/2}$ , where  $C_0$  is a constant depending only on q and  $\lambda$ . We then show that  $\operatorname{pr}(\mathcal{E}_n) \geq 1 - \varepsilon_{n,p}$  for  $\varepsilon_{n,p}$  a positive deterministic sequence converging to zero when  $(\log p)/n \to 0$ .

Under conditions (ii) and (iii) on  $\tau_{\lambda}$ ,

$$\begin{split} &\sum_{v=1}^{p} \left| \tau_{\lambda_{uv}}(\tilde{\sigma}_{uv}) - \sigma_{uv}^{*} \right| = \sum_{v=1}^{p} \left| \tau_{\lambda_{uv}}(\tilde{\sigma}_{uv}) - \sigma_{uv}^{*} \right| \mathbb{1}(|\tilde{\sigma}_{uv}| \geqslant \lambda_{uv}) + \sum_{v=1}^{p} \left| \sigma_{uv}^{*} \right| \mathbb{1}(|\tilde{\sigma}_{uv}| < \lambda_{uv}) \\ &\leqslant 2 \sum_{v=1}^{p} \lambda_{uv} \mathbb{1}(|\sigma_{uv}^{*}| \geqslant \lambda_{uv}) + \sum_{v=1}^{p} \left| \tau_{\lambda_{uv}}(\tilde{\sigma}_{uv}) - \sigma_{uv}^{*} \right| \mathbb{1}(|\tilde{\sigma}_{uv}| \geqslant \lambda_{uv}, |\sigma_{uv}^{*}| < \lambda_{uv}) \\ &+ \sum_{v=1}^{p} |\sigma_{uv}^{*}| \mathbb{1}(|\tilde{\sigma}_{uv}| < \lambda_{uv}) \\ &= T_{1} + T_{2} + T_{3}. \end{split}$$

On the event  $\mathsf{E}_1$ ,  $T_2 \leq 2 \sum_{j=1}^p |\sigma_{uv}^*| \mathbb{1}(|\sigma_{uv}^*| < \lambda_{uv})$  and  $T_3 \leq \sum_{v=1}^p |\sigma_{uv}^*| \mathbb{1}(|\sigma_{uv}^*| < 2\lambda_{uv})$ , where the first inequality uses condition (i) on  $\tau_{\lambda}$  and the second uses the reversed triangle inequality. Therefore, combining the above inequalities and using the fact that  $\lambda_{uv}\mathbb{1}(|\sigma_{uv}^*| \geq \lambda_{uv}) \leq \lambda_{uv}^{1-q} |\sigma_{uv}^*|^q$ , on the event  $\mathsf{E}_2$  we have

$$\sum_{v=1}^{p} \left| \tau_{\lambda_{uv}}(\tilde{\sigma}_{uv}) - \sigma_{uv}^{*} \right| \leq (4 + 2^{1-q}) \sum_{v=1}^{p} \lambda_{uv}^{1-q} |\sigma_{uv}^{*}|^{q} \\ \leq C_0 s_0(p) \left(\frac{\log p}{n}\right)^{(1-q)/2}.$$

Since  $||A||_2 \leq ||A||_1$  for any symmetric matrix A, it remains to bound from below the probability of the event  $\mathcal{E}_n$ . Notice that

$$\tilde{\sigma}_{uu}\tilde{\sigma}_{vv} = \sigma_{uu}^*\sigma_{vv}^* + (\tilde{\sigma}_{uu} - \sigma_{uu}^*)\tilde{\sigma}_{vv} + (\tilde{\sigma}_{vv} - \sigma_{vv}^*)\tilde{\sigma}_{uu} - (\tilde{\sigma}_{uu} - \sigma_{uu}^*)(\tilde{\sigma}_{vv} - \sigma_{vv}^*).$$
(S1)

It therefore follows from Condition 1 that for large n,

$$\operatorname{pr}\left(\tilde{\sigma}_{uu}\tilde{\sigma}_{vv} \geqslant \gamma^2/2 \text{ for all } u, v = 1, \dots, p\right) \geqslant 1 - \frac{\varepsilon_{n,p}}{4},$$
 (S2)

Then we have

$$\operatorname{pr}\left\{\max_{u,v}\frac{|\tilde{\sigma}_{uv} - \sigma_{uv}^{*}|}{(\tilde{\sigma}_{uu}\tilde{\sigma}_{vv})^{1/2}} \geqslant \lambda\left(\frac{\log p}{n}\right)^{1/2}\right\} \leqslant \operatorname{pr}\left[\max_{u,v}|\tilde{\sigma}_{uv} - \sigma_{uv}^{*}| \geqslant \lambda\left\{\frac{\min_{uv}(\tilde{\sigma}_{uu}\tilde{\sigma}_{vv})\log p}{n}\right\}^{1/2}\right]$$
$$\leqslant \operatorname{pr}\left\{\max_{u,v}|\tilde{\sigma}_{uv} - \sigma_{uv}^{*}| \geqslant \lambda\left(\frac{2^{-1}\gamma^{2}\log p}{n}\right)^{1/2}\right\} + \frac{\varepsilon_{n,p}}{4}$$
$$\leqslant \frac{\varepsilon_{n,p}}{2}, \tag{S3}$$

where the second inequality follows from (S2) and the last one from Condition 1. Since Condition 1 and (S1) imply that for n large enough,  $pr(E_2) \ge 1 - \varepsilon_{n,p}/2$ , it follows from (S3) that

$$\operatorname{pr}(\mathcal{E}_n) \ge \operatorname{pr}(\mathcal{E}_n | \mathsf{E}_2) \operatorname{pr}(\mathsf{E}_2) \ge 1 - \varepsilon_{n,p}$$

for large enough n.

*Proof of Theorem* 2. The proof makes use of the following lemmas from Cai et al. (2016).

LEMMA S1. Let A be a symmetric matrix. Then  $||A||_2 \leq ||A||_w \leq ||A||_1$  for all  $1 \leq w \leq \infty$ .

LEMMA S2. Let  $\overline{\Omega}$  be any estimator of  $\Omega^*$  and set  $t_n = \|\overline{\Omega} - \Omega^*\|_{\max}$ . Then on the event  $\{\|\overline{\omega}_v\|_1 \leq \|\omega_v^*\|_1 \text{ for } 1 \leq v \leq p\}$ , we have  $\|\overline{\Omega} - \Omega^*\|_1 \leq 12c_{n,p}t_n^{1-q}$  where  $c_{n,p}$  is the sequence in Condition 4.

The same argument as provided in equation (5) of the main paper shows that  $\tilde{\Sigma}^+$  achieves the same rate of convergence as  $\tilde{\Sigma}$ . By Lemma S1, it suffices to prove that

$$\inf_{\Omega^* \in \mathcal{U}_q} \Pr\Big\{ \|\tilde{\Omega} - \Omega^*\|_1 \leqslant C_0 M_{n,p}^{1-q} c_{n,p} \Big(\frac{\log p}{n}\Big)^{(1-q)/2} \Big\} \geqslant 1 - \varepsilon_{n,p}.$$

To this end, consider  $\|\check{\Omega}^{(1)} - \Omega^*\|_{\max}$ . Since  $1/M_1 \leq \lambda_{\min}(\Omega^*) \leq \lambda_{\max}(\Omega^*) \leq M_1$ , we have  $\max_v(\sigma_{vv}^*) \max_v(\omega_{vv}^*) \leq M_1^2$ . Therefore, by Condition 3 the following bound holds with probability at least  $1 - \varepsilon_{n,p}$ :

$$\begin{split} \|\check{\Omega}^{(1)} - \Omega^{*}\|_{\max} &= \|(\Omega^{*}\check{\Sigma}^{+} - I_{p})\check{\Omega}^{(1)} + \Omega^{*}(I_{p} - \check{\Sigma}^{+}\check{\Omega}^{(1)})\|_{\max} \\ &\leqslant \|(\Omega^{*}\check{\Sigma}^{+} - I_{p})\|_{\max} \|\check{\Omega}^{(1)}\|_{1} + \delta_{n,p} \max_{v} \check{\sigma}_{vv}^{+} \max_{v} \check{\omega}_{vv}^{(1)} \|\Omega^{*}\|_{1} \\ &\leqslant C \|\check{\Omega}^{(1)}\|_{1} \left(\frac{\log p}{n}\right)^{1/2} + 2\delta \|\Omega^{*}\|_{1} \max_{v} \sigma_{vv}^{*} \max_{v} \check{\omega}_{vv}^{(1)} \left(\frac{\log p}{n}\right)^{1/2} \\ &\leqslant C \|\check{\Omega}^{(1)}\|_{1} \left(\frac{\log p}{n}\right)^{1/2} + 2\delta \|\Omega^{*}\|_{1} \max_{v} \sigma_{vv}^{*} \max_{v} \omega_{vv}^{*} \left(\max_{v} \frac{\check{\omega}_{vv}^{(1)}}{\omega_{vv}^{*}}\right) \left(\frac{\log p}{n}\right)^{1/2} \\ &\leqslant C \|\check{\Omega}^{(1)}\|_{1} \left(\frac{\log p}{n}\right)^{1/2} + 2\delta M_{1}^{2} \|\Omega^{*}\|_{1} \left(\max_{v} \frac{\check{\omega}_{vv}^{(1)}}{\omega_{vv}^{*}}\right) \left(\frac{\log p}{n}\right)^{1/2} \end{split}$$
(S4)

for some positive constant *C*. By construction and Condition 4,  $\|\check{\Omega}^{(1)}\|_1 \leq \|\Omega^*\|_1 \leq c_{n,p} \max_v (|\omega_{vv}*|^{1-q})$  and  $\max_v \omega_{vv}^* / \min_v \omega_{vv}^* \leq \lambda_{\max}(\Omega^*) / \lambda_{\min}(\Omega^*) \leq M_1^2$ . Provided  $\check{\omega}_{vv} = O(1)$ , with probability at least  $1 - \varepsilon_{n,p}$ ,  $\|\check{\Omega} - \Omega^*\|_1 \leq KM_{n,p} \{(\log p)/n\}^{1/2}$  for some constant *K*, where  $M_{n,p}$  is as in Condition 4.

45

50

55

By Condition 3,  $\Omega^*$  belongs to the feasible set (9) on an event of probability at least  $1 - \varepsilon_{n,p}$ . Thus, by an analogous argument to that appearing in (S4), we obtain that on the same event,  $\|\tilde{\Omega} - \Omega^*\|_{\max} \leq CM_{n,p} \{(\log p)/n\}^{1/2}$ . It follows from Lemma S2 that on an event of probability at least  $1 - \varepsilon_{n,p}$ ,  $\|\tilde{\Omega} - \Omega^*\|_1 \leq C_0 M_{n,p}^{1-q} c_{n,p} \{(\log p)/n\}^{(1-q)/2}$ , where  $c_{n,p}$  is as in Condition 4.

*Proof of Proposition* 2. The proof relies on the following lemmas due to Liu et al. (2012, Theorem 4.2) and Serfling & Mazumder (2009, Theorem 1).

LEMMA S3. Let  $X_1, \ldots, X_n$  be independent and identically distributed copies of the elliptically distributed random vector X with covariance matrix  $var(X) = \Sigma^* = D^*R^*D^*$ , and let  $R^* = (r_{uv}^*)$  and  $\tilde{R} = (\tilde{r}_{uv})$  be as defined in §4.1 of the main paper. For any  $\delta \in (0, 1)$ ,

$$\Pr\left\{\max_{u,v} |\tilde{r}_{uv} - r_{uv}^*| \ge 3\pi \left(\frac{2\log\delta^{-1}}{5n}\right)^{1/2}\right\} \leqslant \delta.$$

LEMMA S4. Let  $\tilde{\sigma}_{uu}$  be the median absolute deviation estimator of  $\sigma_{uu}^*$  defined in §4·1 of the main paper. Then, for  $\delta = C\varepsilon$  for every  $\varepsilon > 0$  and  $C = 1/F^{-1}(3/4)$ ,

$$\operatorname{pr}\left(\left|\tilde{\sigma}_{uu} - \sigma_{uu}^*\right| > \delta\right) \leqslant 6 \exp(-2n\Delta_{\delta,n}^2),$$

where  $\Delta_{\delta,n} = \min(a_n^*, b_n^*, c_n^*, d_n^*)$  with

$$\begin{split} a_n^* &= \left[ F_u(\nu_u + \delta/2) - \{ \lfloor (n+1)/2 \rfloor - 1 \}/n \right]_+, \\ b_n^* &= \lfloor (n+1)/2 \rfloor/n - F_u(\nu_u - \delta/2), \\ c_n^* &= \left\{ F_u(\nu_u + \sigma_{uu}^* + \delta/2) - F_u(\nu_u - \sigma_{uu}^* - \delta/2) - \lfloor (n+1)/2 \rfloor/n \right\}_+, \\ d_n^* &= \lfloor (n+1)/2 \rfloor/n - \left[ F_u(\nu_u + \sigma_{uu}^* - \delta/2) - F_u(\nu_u - \sigma_{uu}^* + \delta/2) \right]. \end{split}$$

Here  $F_u$  is the distribution function of  $X_u$  and  $\nu_u = F_u^{-1}(1/2)$ .

We now prove Proposition 2. Denote the components of  $\tilde{\Sigma}_R$  by  $\tilde{\Sigma}_R = (\tilde{\sigma}_{uv}^R)$ . Then we have  $\max_{u,v} |\tilde{\sigma}_{uv}^R - \sigma_{uv}^*| \leq \max_{u,v} (|\tilde{\sigma}_{uu}^{1/2} - \sigma_{uu}^{*1/2}||\tilde{r}_{uv}||\tilde{\sigma}_{vv}^{1/2} - \sigma_{vv}^{*1/2}|) + 2\max_{u,v} (|\tilde{\sigma}_{uu}^{1/2} - \sigma_{uu}^{*1/2}||\tilde{r}_{uv}|\sigma_{vv}^{*1/2}) + \max_{u,v} (\sigma_{uu}^{*1/2}|\tilde{r}_{uv} - r_{uv}^*|\sigma_{vv}^{*1/2}).$ 

Thus, with  $\varsigma = \max_u \sigma_{uu}^{*1/2}$  and noting that  $\tilde{r}_{uv} \in [-1, 1]$ , we have

$$\max_{u,v} |\tilde{\sigma}_{uv}^R - \sigma_{uv}^*| \leqslant 2\varsigma \max_u |\tilde{\sigma}_{uu}^{1/2} - \sigma_{uu}^{*1/2}| + \varsigma^2 \max_{u,v} |\tilde{r}_{uv} - r_{uv}^*| + \max_u |\tilde{\sigma}_{uu}^{1/2} - \sigma_{uu}^{*1/2}|^2.$$

<sup>85</sup> We hence obtain, by the Bonferroni inequality,

$$\operatorname{pr}\left(\max_{u,v} |\tilde{\sigma}_{uv}^{R} - \sigma_{uv}^{*}| > t\right) \leq \operatorname{pr}\left(\max_{u} |\tilde{\sigma}_{uu}^{1/2} - \sigma_{uu}^{*1/2}| > \frac{t}{6\varsigma}\right) + \operatorname{pr}\left(\max_{u,v} |\tilde{r}_{uv} - r_{uv}^{*}| > \frac{t}{3\varsigma^{2}}\right) + \operatorname{pr}\left(\max_{u} |\tilde{\sigma}_{uu}^{1/2} - \sigma_{uu}^{*1/2}|^{2} > \frac{t}{3}\right) = P_{1} + P_{2} + P_{3},$$

Taking  $t = C\{(\log p)/n\}^{1/2}$  with  $C = \pi \sqrt{2}/\varsigma^2$  ensures  $P_2 \leq p^{-1}$  by Lemma S3. For  $P_1$ , through a first-order Taylor series expansion with Lagrange remainder, we obtain

$$\max_{u} |\tilde{\sigma}_{uu}^{1/2} - \sigma_{uu}^{*1/2}| \leqslant 2 \max_{u} \bar{Q}_{u}^{-1/2} |\tilde{\sigma}_{uu} - \sigma_{uu}^{*}|,$$

where  $\bar{Q}_u$  lies on a line segment between  $\tilde{\sigma}_{uu}^{1/2}$  and  $\sigma_{uu}^{*1/2}$ . So

$$P_{1} \leq \Pr\left(2\max_{u} \bar{Q}_{u}^{-1/2} | \tilde{\sigma}_{uu} - \sigma_{uu}^{*} | > \frac{t}{6\varsigma}, \max_{u} \bar{Q}_{u}^{-1/2} \leq U\right) + \Pr\left(\max_{u} \bar{Q}_{u}^{-1/2} > U\right)$$
  
$$\leq \Pr\left(\max_{u} | \tilde{\sigma}_{uu} - \sigma_{uu}^{*} | > \frac{t}{12U\varsigma}\right) + \Pr\left(\max_{u} \bar{Q}_{u}^{-1/2} > U\right)$$
  
$$= P_{11} + P_{12}.$$

We have  $P_{11} \leq 6p \exp(-2n\Delta_{\varepsilon,n}^2)$  by the Bonferroni inequality and Lemma S4, where  $\varepsilon = C_0^* \{(\log p)/n\}^{1/2}$  with  $C_0^* = \pi \sqrt{2}/(4U\varsigma)$  and  $\Delta_{\delta,n}$  is defined in Lemma S4. Let  $m_u$  be so the population median of the *u*th variable and let  $f_u$  be the corresponding density function. Then  $b_n^*$  of Lemma S4 satisfies  $b_n^* = f_u(\tilde{m}_u)\delta + O(n^{-1})$ , where  $\tilde{m}_u$  lies on a line segment between  $m_u$  and  $m_u + \delta$ . Since  $f_u$  is continuous in a neighbourhood of the median and  $f_u(m) > 0$  by the elliptical assumption, for  $(\log p)/n$  sufficiently small we have  $f_u(\tilde{m}) = C_1 > 0$ . Then  $b_n^* \ge C_1 C_0^* \{(\log p)/n\}^{1/2}$ . Similar calculations for  $a_n^*$ ,  $c_n^*$  and  $d_n^*$  show that  $\Delta_{\varepsilon,n} \ge C_1 C_0^* \{(\log p)/n\}^{1/2}$ , and so  $P_{11} \le 6p^{1-L}$  for  $L = C_1 C_0^*$ , which is greater than 1 for  $C_0^*$  sufficiently large. This entails  $U < C_1 \pi \sqrt{2}/(4\varsigma)$ . For the control over  $P_{12}$ , we have

$$P_{12} \leqslant \Pr\left(\max_{u} \bar{Q}_{u}^{-1/2} > U, \max_{u} |\tilde{\sigma}_{uu} - \sigma_{uu}^{*}| \leqslant \xi\right) + \Pr\left(\max_{u} |\tilde{\sigma}_{uu} - \sigma_{uu}^{*}| > \xi\right)$$
  
=  $P_{121} + P_{122}$ .

By Bonferroni's inequality and Lemma S4,  $P_{122} \leq 6p \exp(-2n\Delta_{\xi,n}^2)$ . Therefore, by similar arguments to those given for  $P_{11}$ ,  $P_{122}$  can be bounded by a term of order  $p^{-1}$  by taking  $\xi \geq C_2\{(\log p)/n\}^{1/2}$  for  $C_2$  a sufficiently large constant depending only on U and  $\varsigma$ . For  $P_{121}$ ,

$$\max_{u} \bar{Q}_{u}^{-1/2} \leqslant \max_{u} \left[ \{ \min(\tilde{\sigma}_{uu}^{1/2}, \sigma_{uu}^{*1/2}) \}^{-1/2} \right] = \max_{u} \{ \max(\tilde{\sigma}_{uu}^{-1/4}, \sigma_{uu}^{*-1/4}) \}.$$

But on the event  $\{\max_u(|\tilde{\sigma}_{uu} - \sigma_{uu}^*|) \leq \xi\}$ ,  $\sigma_{uu}^* - \xi \leq \tilde{\sigma}_{uu} \leq \sigma_{uu}^* + \xi$  for all  $u \in [p]$ . Therefore

$$P_{121} \leq \Pr\left\{\max_{u}(\sigma_{uu}^* - \xi)^{-1/4} > U\right\} = \Pr\left\{(\min_{u}\sigma_{uu}^* - \xi)^{-1/4} > U\right\} = 0$$

because  $\min_u \sigma_{uu}^* > \xi + U^{-4}$  by assumption.

Proof of Proposition 3. We use the following lemma in the proof.

LEMMA S5 (THEOREM 5 IN FAN ET AL., 2017). Let  $Z_1, \ldots, Z_n$  be real-valued independent identically distributed random variables with  $EZ_1 = \mu^*$  and  $\operatorname{var}(Z_1) = \sigma^{*2}$ . Let  $\delta \in (0, 1)$  be such that  $n^{-1} \log \delta^{-1} \leq 1/8$  and  $H = \{(nv^2)/\log \delta^{-1}\}^{1/2}$ , where  $v \geq \sigma^*$ . Then Huber's *M*-estimator  $\tilde{\mu}^H$  satisfies

$$\operatorname{pr}\left\{ \left| \tilde{\mu}^{H} - \mu \right| \ge 4v \left( \frac{\log \delta^{-1}}{n} \right)^{1/2} \right\} \leqslant 2\delta.$$

If  $(2 + L)(\log p)/n < 1/8$ , Lemma S5 and the union bound guarantee that

$$\Pr\left[\max_{u} |\tilde{\mu}_{u}^{H} - \mu_{u}^{*}| \ge K\{(\log p)/n\}^{1/2}\right] \le 2p^{-(1+L)}$$
(S5)

and

$$\Pr\left[\max_{u,v} |\tilde{\mu}_{uv}^H - \mu_{uv}^*| \ge K\{(\log p)/n\}^{1/2}\right] \le 2p^{-L}.$$
(S6)

105

From (S5) we have, with probability at least  $1 - 2p^{-(1+L)}$ ,

$$\max_{u,v} |\tilde{\mu}_u^H \tilde{\mu}_v^H - \mu_u^* \mu_v^*| \le 2K \max_u |\mu_u^*| \{(\log p)/n\}^{1/2} + K^2 (\log p)/n.$$
(S7)

Combining (S6) and (S7), for large n we have

$$\Pr\left[\max_{u,v} |\tilde{\sigma}_{uv}^H - \sigma_{uv}^*| \ge C\{(\log p)/n\}^{1/2}\right]$$
  
 
$$\leqslant \Pr\left[\max_{u,v} |\tilde{\mu}_{uv}^H - \mu_{uv}^*| + \max_{u,v} |\tilde{\mu}_u^H \tilde{\mu}_v^H - \mu_u^* \mu_v^*| \ge C\{(\log p)/n\}^{1/2}\right]$$
  
 
$$\leqslant 2p^{-L}(1+p^{-1}).$$

<sup>115</sup> Proof of Proposition 4. We will start by stating and proving three auxiliary results. Lemma S6 extends a large deviation result of Petrov (1995) to random variables satisfying Cramér's condition only in a shrinking neighbourhood of zero. Lemma S7 shows that the weights associated with Huber's estimator are uniformly close to 1/n for large n and for all entries of the pilot covariance estimator. Lemma S8 shows that a truncated empirical covariance matrix estimator satisfies Condition 3. More specifically, it considers the truncated empirical mean pilot estimator  $\check{\Sigma}_H = (\check{\sigma}_{uv}^H)$  where  $\check{\sigma}_{uv}^H = n^{-1} \sum_i \mathbb{1}(|X_{iu}X_{iv}| \leq H)X_{iu}X_{iv}$  and  $H = K(n/\log p)^{1/2}$  for some positive constant K. Finally, we show that the difference between  $\check{\Sigma}_H$  and  $\tilde{\Sigma}_H$  is sufficiently small. Thus, the proposition is proved.

LEMMA S6. Let  $X_1$  be a zero-mean random variable with finite variance  $\sigma^2$  and let  $E\{\exp(tX_1)\} < \infty$  in the interval |t| < H, where  $H = O(n^{-\alpha})$  and  $\alpha \in (0, 1/2)$ . If  $x \ge 0$ and  $x = o(n^{1/2}/\log n)$ , then

$$\frac{1 - F_n(x)}{1 - \Phi(x)} = \exp\left\{\left(\frac{x}{n^{1/2}}\right)^3 \lambda\left(\frac{x}{n^{1/2}}\right)\right\} \left\{1 + O\left(\frac{x\log n}{n^{1/2}}\right)\right\},\tag{S8}$$

$$\frac{F_n(-x)}{\Phi(-x)} = \exp\left\{-\left(\frac{x}{n^{1/2}}\right)^3 \lambda\left(\frac{x}{n^{1/2}}\right)\right\} \left\{1 + O\left(\frac{x\log n}{n^{1/2}}\right)\right\},\tag{S9}$$

where  $F_n(x) = \operatorname{pr}(\sum_{i=1}^n X_i < n^{1/2} \sigma x)$ . Here  $\lambda(t) = \sum_{k=0}^{\infty} c_k t^k$  is a power series which will be defined in (S13).

*Proof.* We adapt the arguments of Theorem 5.23 in Petrov (1995) to account for a vanishing constant H. Let h be an arbitrary number in the interval (-H, H) so that  $E\{\exp(hX_1)\} < \infty$ . Denoting the distribution function of  $X_1$  by V(x), we introduce the sequence of random variables  $\bar{X}_n, \ldots, \bar{X}_n$ , with common distribution function defined as

$$\mathrm{d}\bar{V}(x) = \frac{1}{R(h)} \exp(hx) \,\mathrm{d}V(x),$$

where  $R(h) = E\{\exp(hX_1)\} = \int_{-\infty}^{\infty} \exp(hx) \, dV(x)$ . Write

$$\bar{m} = E(\bar{X}_1), \quad \bar{\sigma}^2 = \operatorname{var}(\bar{X}_1), \quad \bar{S}_n = \sum_{j=1}^n \bar{X}_j, \quad \bar{F}_n(x) = \operatorname{pr}(\bar{S}_n - n\bar{m} < x\bar{\sigma}n^{1/2}).$$

For sufficiently small h, we have

$$\log\{R(h)\} = \sum_{\nu=1}^{\infty} \frac{\gamma_{\nu}}{\nu!} h^{\nu},$$

where  $\gamma_{\nu}$  is the cumulant of order  $\nu$  of the random variable  $X_1$ , so  $\gamma_1 = 0$  and  $\gamma_2 = \sigma^2$ . By Petrov (1995, pp. 179–80), choosing h as the unique real root of

$$\sigma t = \bar{m}(h) \tag{S10}$$

for a sufficiently small t, the following expansion of this root h in a power series in t holds:

$$h = \frac{t}{\sigma} - \frac{\gamma_3}{2\sigma^4} t^2 + o(t^2).$$
 (S11)

Then we obtain

$$\frac{t^2}{2} + \log\{R(h)\} - h\bar{m} = t^3\lambda(t),$$
(S12)

where

$$\lambda(t) = \frac{\gamma_3}{6\sigma^3} + \frac{\gamma_4 \sigma^2 - 3\gamma_3^2}{24\sigma^6} t + o(t).$$
 (S13)

Furthermore, by equation (5.78) in Petrov (1995),

$$1 - F_n(\bar{m}\sigma^{-1}n^{1/2}) = \exp\left[n\log\{R(h)\} - nh\bar{m}\right] \int_0^\infty \exp(-hy\bar{\sigma}n^{1/2})\,\mathrm{d}\bar{F}_n(y).$$
(S14)

We now show that

$$\int_0^\infty \exp(-hy\bar{\sigma}n^{1/2})\,\mathrm{d}\bar{F}_n(y) = (2\pi)^{-1/2}\psi(\bar{m}\sigma^{-1}n^{1/2})\Big\{1 + O\big(h\log n\big)\Big\},\tag{S15}$$

where  $\psi(x)$  is the Mills ratio

$$\psi(x) = \frac{1 - \Phi(x)}{\Phi'(x)} = \exp(x^2/2) \int_x^\infty \exp(-y^2/2) \, \mathrm{d}y.$$

Writing  $Q_n(y) = \overline{F}_n(y) - \Phi(y)$ ,

$$\int_0^\infty \exp(-hy\bar{\sigma}n^{1/2}) \,\mathrm{d}\bar{F}_n(y) = (2\pi)^{-1/2} \int_0^\infty \exp(-h\bar{\sigma}n^{1/2}y - y^2/2) \,\mathrm{d}y \\ + \int_0^\infty \exp(-h\bar{\sigma}n^{1/2}y) \,\mathrm{d}Q_n(y) \\ = (2\pi)^{-1/2}I_1 + I_2.$$

For some universal positive constant A and  $n \ge 3$ , Theorem 5.12 in Petrov (1995) gives the two bound

$$|Q_n(y)| \le \frac{An^{-1/2}\log n}{1+y^2}.$$

It follows that

$$\begin{aligned} |I_2| &= \left| Q_n(0) + \int_0^\infty Q_n(y) \operatorname{dexp}(-h\bar{\sigma}n^{1/2}y) \right| \\ &\leqslant An^{-1/2} \log n + An^{-1/2} \log(n) \int_0^\infty \frac{1}{1+y^2} \operatorname{dexp}(-h\bar{\sigma}n^{1/2}y) \\ &= O\left(n^{-1/2} \log n\right). \end{aligned}$$

7

Substituting  $u = h\bar{\sigma}n^{1/2}y$  into  $I_1$ , we obtain

$$I_1 = (h\bar{\sigma}n^{1/2})^{-1} \int_0^\infty \exp\{-u - u^2/(2h^2\bar{\sigma}^2n)\} \,\mathrm{d}u$$

and

$$h\bar{\sigma}n^{1/2}I_1 \leqslant \int_0^\infty \exp(-u)\,\mathrm{d}u = 1, \quad h\bar{\sigma}n^{1/2}I_1 > \int_0^\infty \exp\{-u - u^2/(c^2\sigma^2)\}\,\mathrm{d}u,$$

where the last inequality follows from  $hn^{1/2} > c$  for large n and some positive constant c. Therefore,  $hn^{1/2}I_1 \approx 1$  and

$$\int_0^\infty \exp(-hy\bar{\sigma}n^{1/2}) \,\mathrm{d}\bar{F}_n(y)$$
  
=  $(2\pi)^{-1/2}I_1 + O\left(n^{-1/2}\log n\right) = (2\pi)^{-1/2}I_1\left\{1 + \frac{1}{I_1}O\left(n^{-1/2}\log n\right)\right\}$   
=  $(2\pi)^{-1/2}I_1\left\{1 + O\left(h\log n\right)\right\}.$ 

By substituting into this last expression  $I_1 = \psi(\bar{m}\sigma^{-1}n^{1/2})\{1 + O(h)\}$ , which holds by equation (5.85) in Petrov (1995), we establish (S15).

It follows from equations (S14) and (S15) that

$$\begin{split} &1 - F_n(\bar{m}\sigma^{-1}n^{1/2}) \\ &= (2\pi)^{-1/2} \exp\left[n\log\{R(h)\} - hn\bar{m}\right]\psi(\bar{m}\sigma^{-1}n^{1/2})\Big\{1 + O\big(h\log n\big)\Big\} \\ &= \exp\left[\frac{n\bar{m}^2}{2\sigma^2} + n\log\{R(h)\} - hn\bar{m}\right]\psi(\bar{m}\sigma^{-1}n^{1/2})\{1 - \Phi(\bar{m}\sigma^{-1}n^{1/2})\}\Big\{1 + O\big(h\log n\big)\Big\}. \end{split}$$

<sup>155</sup> Choosing  $t = xn^{-1/2}$  in equation (S10), we have  $x = \bar{m}\sigma^{-1}n^{1/2}$ . Taking into account (S11) and  $h/(t/\sigma) \to 1$ , we finally obtain that for large n,

$$1 - F_n(x) = \{1 - \Phi(x)\} \exp\left\{\left(\frac{x}{n^{1/2}}\right)^3 \lambda\left(\frac{x}{n^{1/2}}\right)\right\} \left\{1 + O\left(\frac{x \log n}{n^{1/2}}\right)\right\}.$$

This proves (S8). The same arguments also imply (S9).

LEMMA S7. Assume  $(6 + L)(\log p)/n < 1/8$  and the conditions of Proposition 3. Let  $\tilde{w}_i^{uv} = \min(1, H/|X_{iu}X_{iv} - \tilde{\sigma}_{uv}^H|)$  for  $u, v = 1, \ldots, p$  and  $i = 1, \ldots, n$ , and write  $a_n \asymp_p b_n$  if  $a_n = O_p(b_n)$  and  $b_n = O_p(a_n)$  as  $n \to \infty$ . Then, for some fixed t > 0, if  $H = K(n/\log p)^{1/2}$ ,

$$\max_{u,v} \Pr\left[ \left| n - \sum_{i=1}^{n} \tilde{w}_{i}^{uv} \right| \leq \left\{ \frac{(2+L)\log p}{n} \right\}^{1/2} \right] \ge 1 - O\{p^{-(2+L)}\}.$$

Proof. It suffices to show that

$$\Pr\left(n - \sum_{i=1}^{n} \tilde{w}_{i}^{uv} \leqslant t\right) \geqslant \left[1 - \exp\left\{-\frac{nt^{2}}{2} + o(1)\right\} - O\{p^{-(4+L)}\}\right], \quad (S16)$$

since if we choose  $t^2 = (4 + L)(\log p)/n$ , Bonferroni's inequality would then give

$$\operatorname{pr}\left(n-\sum_{i=1}^{n} \tilde{w}_{i}^{uv} \leqslant t \; \forall u, v=1,\ldots, p\right) \geqslant 1-\sum_{u\geqslant v} \operatorname{pr}\left(n-\sum_{i=1}^{n} \tilde{w}_{i}^{uv} \geqslant t\right)$$

$$\geqslant 1-\frac{p(p-1)}{2} \max_{u,v} \operatorname{pr}\left(n-\sum_{i=1}^{n} \tilde{w}_{i}^{uv} \geqslant t\right)$$

$$\geqslant 1-p^{2} \exp\left\{-\frac{tn}{2}+o(1)\right\}-O\{p^{-(2+L)}\}$$

$$\geqslant 1-O\{p^{-(2+L)}\}.$$

$$160$$

To prove (S16), first observe that

$$\begin{aligned} &\Pr\left(n - \sum_{i=1}^{n} \tilde{w}_{i}^{uv} \leqslant t\right) \\ &= \Pr\left(\frac{1}{n} \sum_{i=1}^{n} \tilde{w}_{i}^{uv} \geqslant 1 - t/n\right) \\ &= \Pr\left\{\frac{1}{n} \sum_{i=1}^{n} \mathbb{1}(|X_{iu}X_{iv} - \tilde{\sigma}_{uv}^{H}| \leqslant H) + \frac{1}{n} \sum_{i=1}^{n} \frac{\mathbb{1}(|X_{iu}X_{iv} - \tilde{\sigma}_{uv}^{H}| > H)H}{|X_{iu}X_{iv} - \tilde{\sigma}_{uv}^{H}|} \geqslant 1 - t/n\right\} \\ &= \Pr\left\{1 - \frac{1}{n} \sum_{i=1}^{n} \mathbb{1}(|X_{iu}X_{iv} - \tilde{\sigma}_{uv}^{H}| > H)\left(1 - \frac{H}{|X_{iu}X_{iv} - \tilde{\sigma}_{uv}^{H}|}\right) \geqslant 1 - t/n\right\} \\ &\geqslant \Pr\left\{\frac{1}{n} \sum_{i=1}^{n} \mathbb{1}(|X_{iu}X_{iv} - \tilde{\sigma}_{uv}^{H}| > H) \leqslant t/n\right\}.\end{aligned}$$

Further, the arguments of Proposition 3 under the assumption  $(6 + L)(\log p)/n < 1/8$  imply that  $\max_{u,v} |\tilde{\sigma}_{uv}^H - \sigma_{uv}^*| \leq C\{(\log p)/n\}^{1/2}$  with probability at least  $1 - O\{p^{(-4+L)}\}$ . Combining this max norm bound with Hoeffding's inequality, we obtain

$$\operatorname{pr}\left\{\frac{1}{n}\sum_{i=1}^{n}\mathbb{1}(|X_{iu}X_{iv} - \tilde{\sigma}_{uv}^{H}| > H) \leq t/n\right\}$$

$$\geq \operatorname{pr}\left\{\frac{1}{n}\sum_{i=1}^{n}\mathbb{1}(|X_{iu}X_{iv} - \sigma_{uv}^{*}| > H - \max_{u,v}|\tilde{\sigma}_{uv}^{H} - \sigma_{uv}^{*}|) \leq t/n\right\}$$

$$\geq \operatorname{pr}\left\{\frac{1}{n}\sum_{i=1}^{n}\mathbb{1}(|X_{iu}X_{iv} - \sigma_{uv}^{*}| > H - \eta) \leq t/n\right\}\left\{1 - O(p^{-(4+L)})\right\}$$

$$\geq \left[1 - \exp\left\{-\frac{n(t/n - \delta_{H})^{2}}{2}\right\}\right]\left[1 - O\{p^{-(4+L)}\}\right],$$
(S17)
(S18)

where  $\eta \ge C\{(\log p)/n\}^{1/2}$  and  $\delta_H = E\{\mathbb{1}(|X_{iu}X_{iv} - \sigma_{uv}^*| < H - \eta)\}$ . From Markov's inequality,  $\delta_H = O[\{(\log p)/n\}^{1/2}]$ . Then (S17) and simple manipulations establish (S16).  $\Box$ 

LEMMA S8. Let  $\check{\Sigma}_H := (\check{\sigma}_{uv}^H) = n^{-1} \sum_{i=1}^n \mathbb{1}(|X_{iu}X_{iv}| \leq H) X_{iu}X_{iv}$ . Under the conditions of Proposition 4, for large n and  $H = K(n/\log p)^{1/2}$  with  $K \ge 0$  and  $C \ge 0$ ,

$$\Pr\left[\max_{u,v} \left| (\check{\Sigma}_H \Omega^* - I_p)_{uv} \right| \leqslant C\{(\log p)/n\}^{1/2} \right] \ge 1 - \varepsilon_{n,p}$$

where  $\varepsilon_{n,p} \leq C_0 (\log p)^{-1/2} p^{-L}$  for positive constants  $C_0$  and L.

*Proof.* Let  $\nu_{uv} = E\{\sum_{k=1}^{p} \mathbb{1}(|X_{iu}X_{ik}| \leq H)X_{iu}X_{ik}\omega_{kv}^*\};$  then  $\|\Sigma_H\Omega^* - I\|_{\max} = O[\{(\log p)/n\}^{1/2}]$  implies

$$|\nu_{uv} - \mathbb{1}(u=v)| = O[\{(\log p)/n\}^{1/2}].$$
(S19)

180 Note also that

$$\Pr\left\{\left|\sum_{k=1}^{p} \tilde{\sigma}_{uk}^{H} \omega_{kv}^{*} - \mathbb{1}(u=v)\right| \ge \lambda_{n} (\sigma_{uu}^{*} \omega_{vv}^{*})^{1/2}\right\}$$

$$\leq \Pr\left\{\left|\sum_{i=1}^{n} \sum_{k=1}^{p} \mathbb{1}(|X_{iu}X_{ik}| \le H) X_{iu}X_{ik} \omega_{kv}^{*} - n\nu_{uv}\right| \ge n\lambda_{n} (\sigma_{uu}^{*} \omega_{vv}^{*})^{1/2} - n|\mathbb{1}(u=v) - \nu_{uv}|\right\}$$

$$\leq \Pr\left[\frac{1}{n^{1/2}}\left|\sum_{i=1}^{n} \sum_{k=1}^{p} \mathbb{1}(|X_{iu}X_{ik}| \le H) X_{iu}X_{ik} \omega_{kv}^{*} - n\nu_{uv}\right| \ge \delta(\sigma_{uu}^{*} \omega_{vv}^{*}\log p)^{1/2} - O\{(\log p)^{1/2}\}\right]$$
(S20)

Since  $|\mathbb{1}(|X_{iu}X_{ik}| \leq H)X_{iu}X_{ik}| \leq K(n/\log p)^{1/2}$  and  $\max_{u,v} |\omega_{uv}^*| \leq M$  for some M > 0, we have

$$\left| \sum_{k=1}^{p} \mathbb{1}(|X_{iu}X_{ik}| \leqslant H) X_{iu}X_{ik}\omega_{kv}^{*} \right| \leqslant K(n/\log p)^{1/2} \max_{v} \sum_{k=1}^{p} |\omega_{kv}^{*}|$$
  
$$\leqslant \tilde{K}(n/\log p)^{1/2} \max_{v} \sum_{k=1}^{p} |\omega_{kv}^{*}|^{1-q}$$
  
$$\leqslant \tilde{K}(n/\log p)^{1/2} c_{n,p}$$
  
$$= O\{n^{(2-q)/2}/(\log p)^{(4-q)/2}\}.$$

Therefore  $E[\exp\{t\sum_{k=1}^{p} \mathbb{1}(|X_{iu}X_{ik}| \leq H)X_{iu}X_{ik}\omega_{kv}^*\}] < \infty$  as long as we choose  $|t| < O\{(\log p)^{(4-q)/2}/n^{(2-q)/2}\} = O(n^{-(1-q)/3})$ . Thus, taking  $|t| < Cn^{-(1-q)/3}$  for some sufficiently large positive constant C, applying Lemma S6 to (S20) yields

$$pr\left\{ \left| \sum_{k=1}^{p} \tilde{\sigma}_{uk}^{H} \omega_{kv}^{*} - \mathbb{1}(u=v) \right| \ge \lambda_{n} (\sigma_{uu}^{*} \omega_{vv}^{*})^{1/2} \right\} \\ \leqslant \{1+o(1)\} \operatorname{pr}\left\{ |N(0,1)| \ge \delta (\log p)^{1/2} \right\} \leqslant C (\log p)^{-1/2} p^{-\delta^{2}/2}.$$

190

185

Taking  $\delta \leq 2$ , the last inequality and an application of Bonferroni's inequality complete the proof.

We now prove Proposition 4. The strategy is to rewrite the Huber estimator as a weighted mean that behaves essentially like a truncated mean with a diverging level of truncation as n goes to <sup>195</sup> infinity. Writing  $\tilde{w}_i^{uv} = \min(1, H/|X_{iu}X_{iv} - \tilde{\sigma}_{uv}^H|)$  for  $u, v = 1, \ldots, p$  and  $i = 1, \ldots, n$ , it is easy to see that

$$\tilde{\sigma}_{uv}^{H} = \frac{\sum_{i=1}^{n} \tilde{\mathbf{w}}_{i}^{uv} X_{iu} X_{iv}}{\sum_{i=1}^{n} \tilde{\mathbf{w}}_{i}^{uv}}.$$

Hence, letting  $\tilde{\mathbf{w}}_i^u = (\tilde{\mathbf{w}}_i^{u1}, \dots, \tilde{\mathbf{w}}_i^{up})^{\mathrm{T}}$  and  $n_{uv} = \sum_{i=1}^n \tilde{\mathbf{w}}_i^{uv}$ , it follows from Lemma S7 and Proposition 3 that

$$pr\left\{\left|\sum_{k=1}^{p} \tilde{\sigma}_{uk}^{H} \omega_{kv}^{*} - \mathbb{1}(u=v)\right| \ge \lambda_{n} (\sigma_{uu}^{*} \omega_{vv}^{*})^{1/2}\right\} \\
= pr\left\{\left|\sum_{i=1}^{n} \sum_{k=1}^{p} \frac{\tilde{w}_{i}^{uk}}{\sum_{j=1}^{n} \tilde{w}_{j}^{uk}} X_{iu} X_{ik} \omega_{kv}^{*} - \mathbb{1}(u=v)\right| \ge \lambda_{n} (\sigma_{uu}^{*} \omega_{vv}^{*})^{1/2}\right\} \\
\leqslant pr\left\{\left|\sum_{i=1}^{n} \sum_{k=1}^{p} \tilde{w}_{i}^{uk} X_{iu} X_{ik} \omega_{kv}^{*} - \mathbb{1}(u=v)\right| \ge n\lambda_{n} (\sigma_{uu}^{*} \omega_{vv}^{*})^{1/2}\right\} + O\{p^{-(2+L)}\}. \quad (S21)$$

In order to further bound (S21),

$$\begin{aligned} \left| \sum_{i=1}^{n} \sum_{k=1}^{p} \tilde{w}_{i}^{uk} X_{iu} X_{ik} \omega_{kv}^{*} \right| \\ &= \left| \sum_{i=1}^{n} \sum_{k=1}^{p} \left\{ \mathbb{1}(|X_{iu} X_{ik} - \tilde{\sigma}_{uk}^{H}| \leq H) X_{iu} X_{ik} \omega_{kv}^{*} \right\} \right|$$

$$+ \mathbb{1}(|X_{iu} X_{ik} - \tilde{\sigma}_{uk}^{H}| > H) \frac{H}{|X_{iu} X_{ik} - \tilde{\sigma}_{uk}^{H}|} \operatorname{sgn}(X_{iu} X_{ik} - \tilde{\sigma}_{uk}^{H}) \omega_{kv}^{*} \right\} \end{aligned}$$

$$\leq \left| \sum_{i=1}^{n} \sum_{k=1}^{p} \mathbb{1}(|X_{iu} X_{ik} - \tilde{\sigma}_{uk}^{H}| \leq H) X_{iu} X_{ik} \omega_{kv}^{*} \right|$$

$$+ \left| \sum_{i=1}^{n} \sum_{k=1}^{p} \mathbb{1}(|X_{iu} X_{iv} - \tilde{\sigma}_{uv}^{H}| > H) \frac{H}{(X_{iu} X_{ik} - \tilde{\sigma}_{uk}^{H})^{2}} (X_{iu} X_{ik} - \tilde{\sigma}_{uk}^{H}) \omega_{kv}^{*} \right|$$

$$= T_{1} + T_{2}.$$
(S23)

For the second term in (S22), note first that

$$\begin{split} \|\Sigma_H \Omega^* - I\|_{\max} &= \|(\Sigma_H - \Sigma^*) \Omega^*\|_{\max} = \max_{u,v} \left| \sum_{k=1}^p E\{\mathbb{1}(|X_{1u}X_{1k}| > H) X_{1u}X_{1k}\} \omega_{kp}^* \right| \\ &= O[\{(\log p)/n\}^{1/2}]. \end{split}$$

Also observe that by Proposition 3 and Hoeffding's inequality,

$$\frac{1}{n} \sum_{i=1}^{n} \mathbb{1}(|X_{iu}X_{ik} - \tilde{\sigma}_{uk}^{H}| > H) \leqslant \frac{1}{n} \sum_{i=1}^{n} \mathbb{1}(|X_{iu}X_{ik} - \sigma_{uk}^{*}| > H - \eta)$$
$$\leqslant (H - \eta)^{-1} E|X_{1u}X_{1k} - \sigma_{uk}^{*}| + \left\{\frac{\log(p^{2+L})}{2n}\right\}^{1/2}$$
$$= O\left\{\left(\frac{\log p}{n}\right)^{1/2}\right\}$$

with probability at least  $1 - 2p^{-(2+L)}$ , where  $\eta \ge C\{(\log p)/n\}^{1/2}$  and C > 0. Thus, with probability at least  $1 - 2p^{-(2+L)}$ ,

$$T_{2} \leqslant H^{-1} \bigg| \sum_{i=1}^{n} \sum_{k=1}^{p} \mathbb{1}(|X_{iu}X_{iv} - \tilde{\sigma}_{uv}^{H}| > H)(X_{iu}X_{ik} - \tilde{\sigma}_{uk}^{H})\omega_{kv}^{*} \bigg| \\ + \bigg| \sum_{i=1}^{n} \sum_{k=1}^{p} \mathbb{1}(|X_{iu}X_{iv} - \tilde{\sigma}_{uv}^{H}| > H) \frac{(X_{iu}X_{ik} - \tilde{\sigma}_{uk}^{H})^{2} - H^{2}}{H(X_{iu}X_{ik} - \tilde{\sigma}_{uk}^{H})^{2}} (X_{iu}X_{ik} - \tilde{\sigma}_{uk}^{H})\omega_{kv}^{*} \bigg| \\ \leqslant O\{(n\log p)^{1/2}\} + nH^{-1} \sum_{k=1}^{p} \bigg[ \frac{1}{n} \sum_{i=1}^{n} \mathbb{1}(|X_{iu}X_{iv} - \tilde{\sigma}_{uv}^{H}| > H) \big| X_{iu}X_{ik} - \tilde{\sigma}_{uk}^{H} \big| \bigg] |\omega_{kv}^{*}| \\ \leqslant O\{(n\log p)^{1/2}\} + nH^{-2}M^{q} \sum_{k=1}^{p} \bigg[ \frac{1}{n} \sum_{i=1}^{n} \mathbb{1}(|X_{iu}X_{iv} - \tilde{\sigma}_{uv}^{H}| > H) \big( X_{iu}X_{ik} - \tilde{\sigma}_{uk}^{H} \big)^{2} \bigg] |\omega_{kv}^{*}|^{1-q} \\ \leqslant O\{(n\log p)^{1/2}\} + C_{q,\kappa}nH^{-2}c_{n,p} \\ \leqslant O\{(n\log p)^{1/2}\} + o\{(n\log p)^{1/2}\}. \tag{S24}$$

Similar arguments to those used in (S24) can also be used to show that the first term in (S22) satisfies

$$T_1 \leqslant \left| \sum_{i=1}^n \sum_{k=1}^p \mathbb{1}(|X_{iu}X_{ik} - \sigma_{uk}^*| \leqslant H) X_{iu}X_{ik}\omega_{kv}^* \right| + O\{(n\log p)^{1/2}\}$$
(S25)

with probability at least  $1 - 4p^{-(2+L)}$  because for some constant  $\eta \ge C\{(\log p)/n\}^{1/2}$ ,

$$\left|\sum_{i=1}^{n}\sum_{k=1}^{p}\left\{\mathbb{1}(|X_{iu}X_{ik}-\tilde{\sigma}_{uk}^{H}|\leqslant H)-\mathbb{1}(|X_{iu}X_{ik}-\sigma_{uk}^{*}|\leqslant H)\right\}X_{iu}X_{ik}\omega_{kv}^{*}\right|$$

$$\leqslant nM^{q}\sum_{k=1}^{p}\left\{\frac{1}{n}\sum_{i=1}^{n}\left|\mathbb{1}(|X_{iu}X_{ik}-\tilde{\sigma}_{uk}^{H}|\leqslant H)-\mathbb{1}(|X_{iu}X_{ik}-\sigma_{uk}^{*}|\leqslant H)\right||X_{iu}X_{ik}|\right\}|\omega_{kv}^{*}|^{1-q}$$

$$= nM^{q}\sum_{k=1}^{p}\left\{\frac{1}{n}\sum_{i=1}^{n}\left|\mathbb{1}(|X_{iu}X_{ik}-\sigma_{uk}^{*}|>H)\right||X_{iu}X_{ik}|-\mathbb{1}(|X_{iu}X_{ik}-\tilde{\sigma}_{uk}^{H}|>H)\right\}|\omega_{kv}^{*}|^{1-q}$$

$$\leqslant 2nM^{q}\sum_{k=1}^{p}\left\{\frac{1}{n}\sum_{i=1}^{n}\left|\mathbb{1}(|X_{iu}X_{ik}-\sigma_{uk}^{*}|>H-\eta)\right||X_{iu}X_{ik}|\right\}|\omega_{kv}^{*}|^{1-q}.$$

In addition, consider the term  $\nu_{uv} = E\{\sum_{k=1}^{p} \mathbb{1}(|X_{iu}X_{ik} - \sigma_{uk}^*| \leq H)X_{iu}X_{ik}\omega_{kv}^*\}$ ; then  $\|\Sigma_H\Omega^* - I\|_{\max} = O[\{(\log p)/n\}^{1/2}]$  implies

$$|\nu_{uv} - \mathbb{1}(u=v)| = O[\{(\log p)/n\}^{1/2}].$$
(S26)

Therefore, upon combining (S21)–(S26) we see that

$$\operatorname{pr}\left\{\left|\sum_{k=1}^{p} \tilde{\sigma}_{uk}^{H} \omega_{kv}^{*} - \mathbb{1}(u=v)\right| \geq \lambda_{n} (\sigma_{uu}^{*} \omega_{vv}^{*})^{1/2}\right\}$$

$$\leq \operatorname{pr}\left[\left|\sum_{i=1}^{n} \sum_{k=1}^{p} \tilde{w}_{i}^{uk} X_{iu} X_{ik} \omega_{kv}^{*} - n\nu_{uv}\right| + n \left|\nu_{uv} - \mathbb{1}(u=v)\{1-o(1)\}\right| \geq n\lambda_{n} (\sigma_{uu}^{*} \omega_{vv}^{*})^{1/2}\{1-o(1)\}$$

$$+ O\{p^{-(2+L)}\}$$

$$\leq \operatorname{pr}\left[\left|\sum_{i=1}^{n} \sum_{k=1}^{p} \mathbb{1}(|X_{iu} X_{ik} - \sigma_{uk}^{*}| \leq H) X_{iu} X_{ik} \omega_{kv}^{*} - \nu_{uv}\right| \geq n\lambda_{n} (\sigma_{uu}^{*} \omega_{vv}^{*})^{1/2} - O\{(n \log p)^{1/2}\}\right]$$

The proof follows from the last inequality and the arguments of Lemma S8.

*Remark* 1. Unlike the proof of Lemma 1 in Cai et al. (2016), we cannot compute explicitly the mean and variance constants required to standardize  $\sum_{k=1}^{p} \mathbb{1}(|X_{iu}X_{ik} - \sigma_{uk}^*| \leq H)X_{iu}X_{ik}\omega_{kv}^*$ .

*Proof of Proposition* 5. The following auxiliary lemma is a simplified version of Proposition 1 in Lerasle & Oliveira (2011).

LEMMA S9. Let  $Z_1, \ldots, Z_n$  be independent identically distributed random variables with  $E(Z_1) = \mu^*$  and  $\operatorname{var}(Z_1) = (\sigma^*)^2$ . Let  $\delta \in (0, 1)$  and  $M \leq n/2$ , and let  $B_1, \ldots, B_M$  be a regular partition of [n]. Then if  $M \geq \log(\delta^{-1})$ , we have that for some constant  $K \leq 2(6e)^{1/2}$ ,

$$\operatorname{pr}\left\{\tilde{\mu}_M - \mu^* \geqslant K\left(\frac{\sigma^{*2}\log\delta^{-1}}{n}\right)^{1/2}\right\} \leqslant \delta.$$

By Lemma S9 we have that for all  $u, v \in [p]$ ,

$$\Pr\left[|\tilde{\mu}_{u}^{M} - \mu_{u}^{*}| \ge K\{\sigma_{uu}^{*}(\log p)/n\}^{1/2}\right] \le 2p^{-(2+L)}$$

and

$$\Pr\left[|\tilde{\mu}_{uv}^{M} - \mu_{uv}^{*}| \ge K\{\theta_{uv}^{*}(\log p)/n\}^{1/2}\right] \le 2p^{-(2+L)},\tag{S27}$$

where  $\theta_{uv}^* = \operatorname{var}(X_u X_v)$ . Hence, with probability at least  $1 - 2p^{-(1+L)}$ ,

$$\max_{u,v} \left| \tilde{\mu}_u^M \tilde{\mu}_v^M - \mu_u^* \mu_v^* \right| \leqslant 2K \max_{u,v} |\mu_u^*| \{ \sigma_{vv}^* (\log p)/n \}^{1/2} + K^2 \max_u \sigma_{uu}^* (\log p)/n.$$
(S28)

Combining (S27) and (S28), it follows from the union bound that

$$\Pr\left[\max_{u,v} |\tilde{\sigma}_{uv}^M - \sigma_{uv}^*| \ge C\{(\log p)/n\}^{1/2}\right]$$
  
 
$$\leqslant \Pr\left[\max_{u,v} |\tilde{\mu}_{uv}^M - \mu_{uv}^*| + \max_{u,v} |\tilde{\mu}_u^M \tilde{\mu}_v^M - \mu_u^* \mu_v^*| \ge C\{(\log p)/n\}^{1/2}\right]$$
  
 
$$\leqslant 2p^{-L}(1+p^{-1}).$$

*Proof of Proposition* 6. It is easy to check that for any  $\mu'$  and  $\mu''$  such that  $\mu'' - \mu' \ge 0$ ,

$$\psi_H(Z_i - \mu') - \psi_H(Z_i - \mu'') \ge (\mu'' - \mu') \mathbb{1}(Z_i - \mu'' < H, Z_i - \mu' > -H),$$

13

240

250

 $+ O\{p^{-(2+L)}\}.$ 

where  $\psi_H(\cdot)$  is defined in (11). We consider the cases  $\mu \ge \tilde{\mu}^H$  and  $\tilde{\mu}^H \ge \mu$  in turn. If  $\mu \ge \tilde{\mu}^H$ , we obtain

$$\mu - \tilde{\mu}^{H} \leq \left| \frac{1}{n \tilde{p}^{H}} \sum_{i=1}^{n} \psi_{H}(Z_{i} - \mu) - \frac{1}{n \tilde{p}^{H}} \sum_{i=1}^{n} \psi_{H}(Z_{i} - \tilde{\mu}^{H}) \right| = \frac{1}{\tilde{p}^{H}} \left| \frac{1}{n} \sum_{i=1}^{n} \psi_{H}(Z_{i} - \mu) \right|,$$
(S29)

where  $\tilde{p}^{H} = n^{-1} \sum_{i=1}^{n} \mathbb{1}(Z_{i} - \tilde{\mu}^{H} < H, Z_{i} - \mu > -H)$  and the last equality follows from the definition of  $\tilde{\mu}^{H}$ . If  $\tilde{\mu}^{H} \ge \mu$ , we obtain a similar expression to (S29) but with  $\tilde{p}^{H} = n^{-1} \sum_{i=1}^{n} \mathbb{1}(Z_{i} - \mu < H, Z_{i} - \tilde{\mu}^{H} > -H)$ . With both definitions of  $\tilde{p}^{H}$ ,  $\tilde{p}^{H} \ge 1 - n^{-1} \sum_{i=1}^{n} \mathbb{1}(|Z_{i} - \mu| \ge H)$ . Hence, by Bernstein's inequality followed by Markov's inequality, with probability at least  $1 - \delta/2$ ,

265

$$\tilde{p}^{H} \ge 1 - \operatorname{pr}(|Z_{i} - \mu| \ge H) - \left\{\frac{2\log(2\delta^{-1})}{n}\right\} - \frac{\log(2\delta^{-1})}{3n}$$

$$= 1 - \operatorname{pr}\left\{|Z_{i} - \mu|^{1+\varepsilon} \ge \frac{vn}{\log(2\delta^{-1})}\right\} - \left\{\frac{2\log(2\delta^{-1})}{n}\right\} - \frac{\log(2\delta^{-1})}{3n}$$

$$\ge 1 - \frac{4\log(2\delta^{-1})}{3n} - \left\{\frac{2\log(2\delta^{-1})}{n}\right\}.$$
(S30)

It remains to bound  $n^{-1} \sum_{i=1}^{n} \psi_H(Z_i - \mu)$ . Note that

$$E\{\psi_{H}(Z_{i}-\mu)\} = E\{(Z_{i}-\mu)\mathbb{1}(|Z_{i}-\mu| \leq H)\} + HE\{\operatorname{sgn}(Z_{i}-\mu)\mathbb{1}(|Z_{i}-\mu| > H)\}$$
  
$$\leq E\{(Z_{i}-\mu)\mathbb{1}(|Z_{i}-\mu| > H)\} + E\{|Z_{i}-\mu|\mathbb{1}(|Z_{i}-\mu| > H)\}$$
  
$$\leq 2E(|Z_{i}-\mu|^{1+\varepsilon}H^{-\varepsilon})$$
  
$$\leq \frac{2v}{H^{\varepsilon}}.$$

Therefore, by Bernstein's inequality, with probability at least  $1 - \delta/2$ ,

$$\frac{1}{n}\sum_{i=1}^{n}\psi_H(Z_i-\mu) \leqslant \frac{2v}{H^{\varepsilon}} + \left\{\frac{2vH^{1-\varepsilon}\log(2\delta^{-1})}{n}\right\} + \frac{H\log(2\delta^{-1})}{3n}.$$
 (S31)

Combining (S29)–(S31) and Bonferroni's inequality, with probability at least  $1 - \delta$ ,

$$\begin{split} \tilde{\mu}^{H} - \mu &\leqslant \left[1 - \frac{4\log(2\delta^{-1})}{3n} - \left\{\frac{2\log(2\delta^{-1})}{n}\right\}^{1/2}\right]^{-1} \left[\frac{2v}{H^{\varepsilon}} + \left\{\frac{2vH^{1-\varepsilon}\log(2\delta^{-1})}{n}\right\}^{1/2} + \frac{H\log(2\delta^{-1})}{3n}\right] \\ &= \left[1 - \frac{4\log(2\delta^{-1})}{3n} - \left\{\frac{2\log(2\delta^{-1})}{n}\right\}^{1/2}\right]^{-1} \frac{7 + \sqrt{2}}{3} v^{1/(1+\varepsilon)} \left\{\frac{\log(2\delta^{-1})}{n}\right\}^{\varepsilon/(1+\varepsilon)}. \end{split}$$

$$(S32)$$

Finally, it follows from  $n > 12 \log(2\delta^{-1})$  that  $4 \log(2\delta^{-1})/(3n) - \{2 \log(2\delta^{-1})/n\}^{1/2} \le 1/3$  and therefore (S32) gives

$$\tilde{\mu}^H - \mu \leqslant \frac{7 + \sqrt{2}}{2} v^{1/(1+\varepsilon)} \left\{ \frac{\log(2\delta^{-1})}{n} \right\}^{\varepsilon/(1+\varepsilon)}$$

with probability at least  $1 - \delta$ .

*Proof of Theorem* 3. Using Corollary 1 and the arguments of Proposition 3, we obtain the elementwise max norm bound

$$\Pr\left[\max_{u,v} |\tilde{\sigma}_{uv} - \sigma_{uv}^*| \leqslant K \{(\log p)/n\}^{\varepsilon/(2+\varepsilon)}\right] \ge 1 - O(p^{-L}).$$

The proof is completed by inspection of the arguments given for the proof of Theorem 1.  $\Box$  275

*Proof of Theorem* 4. Using Corollary 1 and the arguments of Proposition 4, we obtain the elementwise max norm bound

$$\Pr\left[\max_{u,v} \left| (\tilde{\Sigma}_H \Omega^* - I_p)_{uv} \right| \leqslant K \{ (\log p)/n \}^{\varepsilon/(2+\varepsilon)} \right] \ge 1 - O(p^{-L}).$$

The proof is completed by inspection of the arguments given for the proof of Theorem 2.  $\Box$ 

#### S2. DISCUSSION

We first discuss Theorems 1 and 2 by emphasizing the consequences of the technical conditions we impose on the paramater spaces. We then justify a technical condition required in the proof of Proposition 4. Finally, we show that pilot estimators meeting Condition 1 but not Condition 3 lead to consistent estimation of the precision matrix with suboptimal rates of convergence.

#### S2.1. Technical conditions of Theorems 1 and 2

In Theorems 1 and 2, we assume that the diagonal elements of  $\Sigma^*$  and  $\Omega^*$  are bounded away from zero and infinity. In this work, we prioritize the relaxation of sub-Gaussian assumptions as we believe they are unrealistic in high-dimensional settings.

Our assumption  $\min_u(\sigma_{uu}^*) = \gamma > 0$ , in Theorem 1, is very similar to the one appearing in equation (14) of Cai & Liu (2011). In that paper  $\min_{u,v} \operatorname{var}(X_u X_v) \ge \tau > 0$  is assumed, even when X is multivariate normal. Note that our assumptions on  $\min_u \sigma_{uu}^*$  and  $\max_u \sigma_{uu}^*$  are also implied by  $0 < c \le \lambda_{\min}(\Sigma^*) \le \lambda_{\max}(\Sigma^*) \le C < \infty$ . The latter is arguably a rather mild regularity condition, which has appeared in many papers (e.g., Bickel & Levina, 2008; Rothman et al., 2009; Fan et al., 2013).

#### S2.2. Bounding the max-norm error of the partial population covariance matrix

In Proposition 4 we verified that the Huber estimator satisfies Condition 3 under the assumption that  $\|\Sigma_H \Omega^* - I\|_{\max} = O[\{(\log p)/n\}^{1/2}]$ . The following lemma gives three sufficient conditions that guarantee this max-norm error bound.

LEMMA S10. Assuming E(X) = 0 and  $\log p = o(n)$ , under either of the following scenarios we have that  $\|\Sigma_H \Omega^* - I\|_{\max} = O[\{(\log p)/n\}^{1/2}]$  for  $H = K(n/\log p)^{1/2}$ , where K is a large enough constant.

- (i) For any  $\nu \in \mathbb{R}^p$ ,  $X^{\mathsf{T}}\nu$  is sub-Gaussian with parameter  $\kappa_0^2 \|\nu\|_2^2$ , i.e.,  $E\{\exp(tX^{\mathsf{T}}\nu)\} \leq E\{\exp(t^2\kappa_0^2\|\nu\|_2^2/2)\}$  for any  $t \in \mathbb{R}$ . Furthermore,  $\log p = O(n^{\alpha})$  and  $M_{n,p} = O(n^{\tau})$  for some  $\alpha \in [0, 1)$  and  $\tau > 0$ .
- (ii) For all u = 1, ..., p,  $E(X_u^4) < \infty$  and  $M_{n,p} = O(1)$ .
- (iii) For all u, v = 1, ..., p and  $\varepsilon \in (0, 1)$ , we have  $E(|X_u X_v|^{2+\varepsilon}) < \infty$  and  $M_{n,p} = 0$  $O\{(n/\log p)^{\varepsilon/2}\}.$

15

Proof. First note that

$$\left| (\Sigma_{H} \Omega^{*})_{uv} - \mathbb{1}(u = v) \right| = \left| (\sigma_{u.}^{H})^{\mathsf{T}} \omega_{.v}^{*} - \mathbb{1}(u = v) \right| = \left| \sum_{k=1}^{p} |\sigma_{uk}^{H} \omega_{kv}^{*} - \mathbb{1}(u = v) \right|$$
$$= \left| \sum_{k=1}^{p} E\{X_{u} X_{k} \,\mathbb{1}(|X_{u} X_{k}| \leqslant H)\} \omega_{kv}^{*} - \mathbb{1}(u = v) \right|$$
$$= \left| \sum_{k=1}^{p} E\{X_{u} X_{k} \,\mathbb{1}(|X_{u} X_{k}| > H)\} \omega_{kv}^{*} \right|$$
$$\leqslant \max_{k} E\{|X_{u} X_{k}| \,\mathbb{1}(|X_{u} X_{k}| > H)\} \sum_{k=1}^{p} |\omega_{kv}^{*}|$$
$$\leqslant M_{n,p} \max_{k} E\{|X_{u} X_{k}| \,\mathbb{1}(|X_{u} X_{k}| > H)\}.$$
(S33)

310

We will complete the proof by separately showing that the right-hand side of the last inequality is 
$$o(1)$$
 under the three different settings of the lemma.

(i) First we rewrite  $X_u X_k$  as a quadratic form  $X_u X_k = X^T B X$ , where *B* is a  $p \times p$  matrix with  $B_{ku} = B_{uk} = 1$  and zeros in all other components. Exploiting the sub-Gaussian tails of *X* and Theorem 2.1 of Hsu et al. (2012), we see that for t > 2,

$$pr\{|X_u X_k - E(X_u X_k)| > 2\kappa_0^2 t\} \leqslant \exp(-t).$$
(S34)

Applying the Cauchy–Schwarz inequality followed by the triangle inequality and (S34), we obtain

320

$$E\{|X_u X_k| \ \mathbb{1}(|X_u X_k| > H)\} \\ \leqslant \{E(X_u X_k)^2\}^{1/2} \{\operatorname{pr}(|X_u X_k| > H)\}^{1/2} \\ \leqslant \{E(X_u X_k)^2\}^{1/2} \{\operatorname{pr}(|X_u X_k - E(X_u X_k)| > H - |E(X_u X_k)|\}^{1/2} \\ \leqslant \{E(X_u X_k)^2\}^{1/2} (\exp[-\{H - |E(X_u X_k)|\}/(2\kappa_0^2)])^{1/2} \\ = O[\exp\{-c(n/\log p)^{1/2}\}] \\ = O\{\exp(-n^{1-\alpha})\}$$

325

for some constant c > 0. Combining this exponential tail decay bound with (S33), we see that the claimed result holds as long as  $M_{n,p} = O(n^{\tau})$  where  $\tau > 0$ .

(ii) Applying the Cauchy-Schwarz, triangle and Chebychev's inequalities gives

330

$$E\{|X_{u}X_{k}| 1|(|X_{u}X_{k}| > H)\} \\ \leq \{E(X_{u}X_{k})^{2}\}^{1/2}\{pr(|X_{u}X_{k}| > H)\}^{1/2} \\ \leq \{E(X_{u}X_{k})^{2}\}^{1/2}\{pr(|X_{u}X_{k} - E(X_{u}X_{k})| > H - |E(X_{u}X_{k})|\}^{1/2} \\ \leq \frac{\{E(X_{u}X_{k})^{2}\}^{1/2}\{var(X_{u}X_{k})\}^{1/2}}{|H - |E(X_{u}X_{k})||} \\ = O\left\{\left(\frac{\log p}{n}\right)^{1/2}\right\}.$$

Using this result and  $M_{n,p} = O(1)$  in (S33) establishes the second claim.

(iii) Applying the Cauchy-Schwarz inequality yields

$$E\{|X_u X_k| \mathbb{1}(|X_u X_k| > H)\} = E\{|X_u X_k| \mathbb{1}(|X_u X_k| > H)\mathbb{1}(|X_u X_k| > H)\} \le [E\{(X_u X_k)^2 \mathbb{1}(|X_u X_k| > H)\}]^{1/2}\{\operatorname{pr}(|X_u X_k| > H)\}^{1/2}.$$
(S35)

Furthermore,

$$E\{(X_u X_k)^2 \mathbb{1}(|X_u X_k| > H)\} = E\{|X_u X_k|^{2+\varepsilon} |X_u X_k|^{-\varepsilon} \mathbb{1}(|X_u X_k| > H)\}$$

$$\leq E(|X_u X_k|^{2+\varepsilon}) H^{-\varepsilon}$$

$$= O\left\{\left(\frac{\log p}{n}\right)^{\varepsilon/2}\right\},$$
(S36)

and by the triangle inequality followed by Markov's inequality we obtain

$$pr(|X_uX_k| > H) \leq pr\{|X_uX_k - E(X_uX_k)| > H - |E(X_uX_k)|\}$$

$$= pr[|X_uX_k - E(X_uX_k)|^{2+\varepsilon} > |H - |E(X_uX_k)||^{2+\varepsilon}]$$

$$\leq \frac{E\{|X_uX_k - E(X_uX_k)|^{2+\varepsilon}\}}{|H - |E(X_uX_k)||^{2+\varepsilon}}$$

$$= O\left\{\left(\frac{\log p}{n}\right)^{1+\varepsilon/2}\right\}.$$
(S37)

From (S35), (S36) and (S37) we see that

$$E\{|X_uX_k| \ \mathbb{1}(|X_uX_k| > H)\} = O\left\{\left(\frac{\log p}{n}\right)^{(1+\varepsilon)/2}\right\}$$

which, combined with  $M_{n,p} = O\{(n/\log p)^{\varepsilon/2}\}$  and (S33), verifies the third claim.

Scenarios (i) and (ii) of the above lemma are benchmark settings under which other pilot estimators satisfy Condition 3. More specifically, on the one hand, (i) assumes sub-Gaussian tails and is therefore a scenario where the sample covariance leads to optimal rates of convergence (Cai et al., 2016); on the other hand, (ii) entails that  $M_{n,p}$  is bounded, and, as mentioned in § 3 of the main paper, in this case the three robust pilot estimators presented in the paper can be shown to satisfy Condition 3 while the sample covariance fails as shown in Proposition 1. Scenario (iii) is the most interesting as it allows for both heavy tails and a diverging  $M_{n,p}$ .

#### S2.3. Convergence rate of pilot estimators that satisfy Condition 1 but not Condition 3

The following proposition shows that pilot estimators satisfying Condition 1 but not Condition 3 can still lead to consistent precision matrix estimators but with a slower rate.

**PROPOSITION S1.** Suppose that Conditions 1 and 4 are satisfied. Under the scaling condition  $\log p = o(n)$  we have, for a constant  $C_0 > 0$ ,

$$\inf_{\Omega^* \in \mathcal{G}_q} \Pr\left\{ \|\tilde{\Omega} - \Omega^*\|_2 \leqslant C_0 M_{n,p}^{2-2q} c_{n,p} \left(\frac{\log p}{n}\right)^{(1-q)/2} \right\} \geqslant 1 - \varepsilon_{n,p},$$

where  $\varepsilon_{n,p}$  is a deterministic sequence that decreases to zero as  $n, p \to \infty$  and  $\tilde{\Omega}$  is the robust adaptively constrained  $\ell_1$ -minimization estimator described in (7)–(10) of the main paper with  $\lambda_{n,p} = \lambda M_{n,p} \{(\log p)/n\}^{1/2}$  and  $\lambda > 0$ .

335

17

Fig. S1. QQ-plots for the three genes ME1, IRF3 and ACSL1.

*Proof.* We only sketch the arguments since they are essentially the same as those for Theorem 2. Following (S4) and the subsequent arguments but using the weaker bound  $\|\tilde{\Sigma}\Omega^* - I\|_{\max} = O(M_{n,p}\{(\log p)/n\}^{1/2})$ , we can show that with probability  $1 - \varepsilon_{n,p}$ ,

$$\|\tilde{\Omega} - \Omega^*\|_{\max} \leqslant CM_{n,p}^2 \left(\frac{\log p}{n}\right)^{1/2}$$

for some constant C > 0. Then it follows from Lemma S2 that on an event of probability at least  $1 - \varepsilon_{n,p}, \|\tilde{\Omega} - \Omega^*\|_2 \leq \|\tilde{\Omega} - \Omega^*\|_1 \leq C_0 M_{n,p}^{2-2q} c_{n,p} (\log p/n)^{(1-q)/2}.$ 

#### S3. Additional plot for the real-data example

Figure S1 shows a QQ-plot of the three genes (ME1, IRF3 and ACSL1) whose expression contains outliers.
