

Parameter Estimation for Multiscale Diffusions: An Overview

G. A. Pavliotis*, Y. Pokern†, A.M. Stuart‡

September 19, 2008

1 Introduction

There are many applications where it is desirable to fit reduced stochastic descriptions (eg SDEs) to data. These include molecular dynamics [28], [6], atmosphere/ocean science [13], cellular biology [2] and econometrics [4]. The data arising in these problems often has a multiscale character and may not be compatible with the desired diffusion at small scales (see [8], [14], [11], [1] and [20]). The question then arises as to how to optimally employ such data to find a useful diffusion approximation.

In this chapter we illustrate the issues arising from multiscale data, first through studying some illustrative examples in Section 2 and then more generally in the context of averaging and homogenization for diffusions in Section 3. In Section 4 we show how subsampling may be used to remove some of the problems arising from multiscale data. Sections 5 and 6 show two alternative approaches designed to deal with multiscale data, namely the use of hypoelliptic diffusions and ideas stemming from nonparametric drift estimation. Hypoelliptic diffusions are appropriate for data which is smooth (by which we mean that it is of greater regularity than Brownian motion, e.g. differentiable) at small scales, and for which physical principles dictate a damped driven Hamiltonian model. Nonparametric drift estimation, a topic intimately related to the use of the local time (empirical measure) of the data, rather than time-ordered information, is useful precisely because it does not use time-ordering, and hence does not use small scale information.

The material in this overview is based, to a large extent, on the papers [18], [19], [21], [24], [25]. We have placed the material in a common framework, aiming to highlight the interconnections in this work. The details, however, are in the original papers.

2 Illustrative Examples

In this section we start with three examples to illustrate the primary issue arising in this context. To understand these examples it is necessary to understand the concept of the quadratic variation process for a diffusion. Consider the stochastic differential equation (SDE)

$$\frac{dz}{dt} = h(z) + \gamma(z) \frac{dW}{dt}, \quad z(0) = z_0. \quad (1)$$

Here $z(t) \in \mathcal{Z}$ with $\mathcal{Z} = \mathbb{R}^d$ or \mathbb{T}^d . We assume that h, γ are Lipschitz on \mathcal{Z} . To make the notion of solution precise we let \mathcal{F}_t denote the filtration generated by $\{W(s)\}_{0 \leq s \leq t}$ and define $z(t)$ to be the unique \mathcal{F}_t -adapted process which is a semimartingale defined via the integral equation

$$z(t) = z_0 + \int_0^t h(z(s)) ds + \int_0^t \gamma(z(s)) dW(s). \quad (2)$$

The stochastic integral is interpreted in the Itô sense. It is an \mathcal{F}_t -martingale and we write

$$m(t) = \int_0^t \gamma(z(s)) dW(s). \quad (3)$$

A matrix valued process $Q(t)$ is increasing if $Q(t) - Q(s)$ is non-negative for all $t \geq s \geq 0$. The quadratic variation process of z , namely $\langle z \rangle_t := Q(t)$ is defined as the unique adapted, increasing and continuous process for which

$$m(t)m(t)^T - Q(t)$$

is an \mathcal{F}_t -martingale, see [26] for a definition. The quadratic variation is non-zero precisely because of the lack of regularity of sample paths of diffusion processes. It is given by the expression

$$Q(t) = \int_0^t \gamma(z(s)) \gamma(z(s))^T ds.$$

It is possible to give a corresponding differential statement, namely that

$$\lim_{\tau \rightarrow 0} \sum_{i=0}^{n-1} (z(t_{i+1}) - z(t_i)) (z(t_{i+1}) - z(t_i))^T = Q(T) \quad \text{in prob.} \quad (4)$$

where the ordered times $t_0 = 0 < t_1 < \dots < t_{n-1} < t_n = T$ on $[0, T]$ are such that their largest distance $\tau = \max_{i=1, \dots, n} (t_i - t_{i-1})$ decreases like $\mathcal{O}(1/n)$. An easily accessible treatment for one dimensional continuous local martingales including this result (Theorems 3.1 and 3.8) is given in [5]. The issue of the required decay of τ is treated more carefully in [15].

If γ is constant then

$$Q(t) = t\gamma\gamma^T.$$

Notice that, for ordinary differential equations (ODEs) where $\gamma \equiv 0$ the quadratic variation is zero. The definition we have given here may be generalized from solutions of SDEs to Itô processes where the drift depends upon the past history of $z(t)$. In this fashion it is possible to talk about the quadratic variation associated with a single component of a system of SDEs in several dimensions.

2.1 Example 1. SDE From ODE

This example is taken from [16].

Consider the scale-separated system of ODEs

$$\begin{aligned}\frac{dx}{dt} &= \frac{1}{\epsilon} f_0(y) + f_1(x, y), & x(0) &= \xi, \\ \frac{dy}{dt} &= \frac{1}{\epsilon^2} g_0(y), & y(0) &= \eta,\end{aligned}$$

where $x \in \mathbb{R}^d$. We make some technical assumptions on y (detailed in [16]) which imply that it is mixing with invariant measure μ . We assume that

$$\mathbb{E}^\mu f_0(y) = 0.$$

This ensures that the first term on the right hand side of the equation for x gives rise to a well-defined limit as $\epsilon \rightarrow 0$. In fact this term will be responsible for the creation of white noise in the limiting equation for x . The technical assumptions imply that

$$\frac{1}{\epsilon} \int_0^t f_0(y(s)) ds \Rightarrow \sqrt{2\Sigma} W(t)$$

for some covariance matrix $\Sigma \in \mathbb{R}^{d \times d}$, and W a standard d -dimensional Brownian motion. Here, \Rightarrow denotes weak convergence in $C([0, T], \mathbb{R}^d)$. Intuitively, this weak convergence follows because y has correlation decay with timescale $1/\epsilon^2$ so that $\frac{1}{\epsilon} f_0(y)$ has an autocorrelation function which approximates a Dirac delta distribution.

Now define

$$F(x) = \mathbb{E}^\mu f_1(x, y)$$

which will become the mean drift in the limiting equation for x .

Theorem 1. *Let $\eta \sim \mu$. Then, under the technical conditions on the fast process y stated in [16], $x \Rightarrow X$ in $C([0, T], \mathbb{R}^d)$ as $\epsilon \rightarrow 0$, where*

$$\frac{dX}{dt} = F(X) + \sqrt{2\Sigma} \frac{dW}{dt}, \quad X(0) = \xi.$$

The important point that we wish to illustrate with this example is that the limit of X , and x itself, have vastly different properties at small scales. In particular, the quadratic variations differ:

$$\langle x \rangle_t = 0; \quad \langle X \rangle_t = 2\Sigma t.$$

Any parameter estimation procedure which attempts to fit an SDE in X to data generated by the ODE in x will have to confront this issue. Specifically any parameter estimation procedure which sees small scales in the data will have the potential to *incorrectly* identify an appropriate SDE fit to the data.

2.2 Example 2. Smoluchowski from Langevin

The situation arising in the previous example can also occur when considering scale-separated SDEs. We illustrate this with a physically interesting example taken from [19]: consider the *Langevin equation* for $x \in \mathbb{R}^d$:

$$\epsilon^2 \frac{d^2 x}{dt^2} + \frac{dx}{dt} + \nabla V(x) = \sqrt{2\sigma} \frac{dW}{dt}.$$

As a first order system this is

$$\begin{aligned} \frac{dx}{dt} &= \frac{1}{\epsilon} y, \\ \frac{dy}{dt} &= -\frac{1}{\epsilon} \nabla V(x) - \frac{1}{\epsilon^2} y + \sqrt{\frac{2\sigma}{\epsilon^2}} \frac{dW}{dt}. \end{aligned}$$

Using the method of homogenization the following may be proved:

Theorem 2. [22] As $\epsilon \rightarrow 0$, $x \Rightarrow X$ in $C([0, T], \mathbb{R}^d)$ where X is the solution of the Smoluchowski equation¹

$$\frac{dX}{dt} = -\nabla V(X) + \sqrt{2\sigma} \frac{dW}{dt}.$$

Thus, similarly to the previous example,

$$\langle x \rangle_t = 0; \quad \langle X \rangle_t = 2\sigma t.$$

Any parameter estimation procedure for the SDE in X , and which sees small scales in the data x , will have the potential to incorrectly identify an appropriate homogenized SDE fit to the data.

2.3 Example 3. Butane

The data presented in this example is taken from [23]. We consider a classical molecular dynamics model for butane. The model comprises the positions x and momenta of four (extended) atoms interacting with one another through various two, three and four body interactions, such as bond angle, bond stretch and dihedral angle interactions all combined in a potential $V(x)$. The equations of motion are

$$M \frac{d^2 x}{dt^2} + \gamma M \frac{dx}{dt} + \nabla V(x) = \sqrt{2\gamma k_B T M} \frac{dB}{dt}. \quad (5)$$

¹In molecular dynamics, this equation would be termed *Brownian Dynamics*, whereas in the statistical literature it is sometimes called the *Langevin equation*.

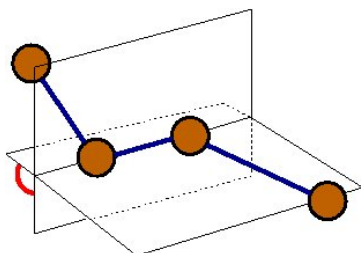

Figure 1: The butane molecule

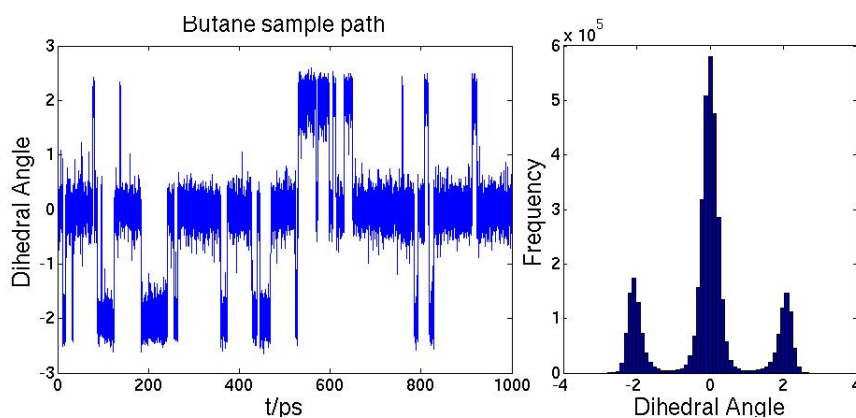

Figure 2: The dihedral angle (time series and histogram)

The choice $\gamma = 0$ gives deterministic dynamics, whilst for $\gamma > 0$ stochastic dynamics are obtained. A typical configuration of the molecule is shown in Figure 1. The *dihedral angle* ϕ is the angle formed by intersecting the planes passing through the first three atoms and through the last three atoms respectively. The molecule undergoes conformational changes which can be seen in changes in the dihedral angle. This is shown in Figure 2 which exhibits a time series for the dihedral angle, as well as its histogram, for $\gamma > 0$. Clearly the dihedral angle has three preferred values, corresponding to three different molecular conformations. Furthermore the transitions between these states is reminiscent of thermally activated motion in a three well potential. This fact concerning the time series remains true even when $\gamma = 0$.

It is hence natural to try and fit an SDE to the dihedral angle, and we

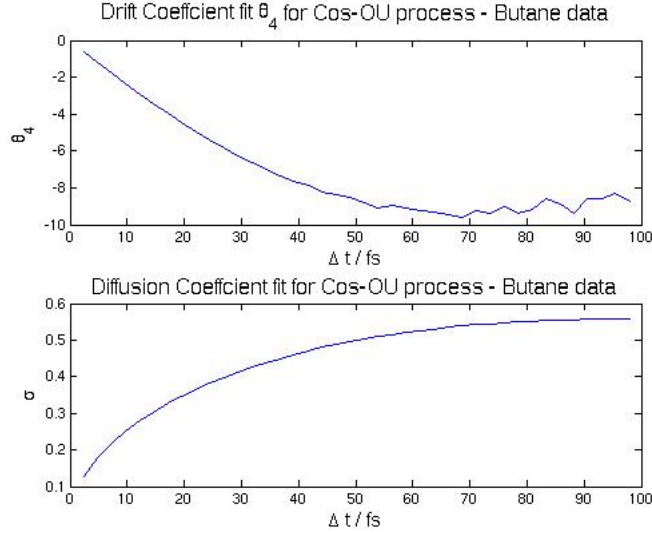

Figure 3: Parameter fits to θ_4 and σ from (6) given data from Figure 2.

consider an SDE of the form

$$\frac{d\Phi}{dt} = -\Psi'(\Phi) + \sigma \frac{dW}{dt}, \quad (6a)$$

$$\Psi(\phi) = \sum_{j=1}^5 \theta_j (\cos(\phi))^j, \quad (6b)$$

where $\{\theta_j\}_{j=1}^5$ and σ are the parameters to be estimated. However, the fit to such an SDE is highly sensitive to the rate at which the data is sampled, as shown in Figure 3. Here the diffusion coefficient is estimated exploiting (4), and the maximum likelihood principle is used to estimate θ .

The behaviour of the estimator at different scales is caused by the fact that the data is again incompatible with the diffusion approximation at small scales. The true dihedral angle ϕ has zero quadratic variation because it is a function of the positions of x only, and not the momenta $M\dot{x}$; only the momenta are directly forced by noise. Thus $\langle \phi \rangle_t = 0$. In contrast, for the model (6), we have $\langle \Phi \rangle_t = \sigma^2 t$. Notice that the estimated σ in Figures 3 and 5 tends to zero as the sampling rate increases, reflecting the smoothness of the data at small scales. Because the maximum likelihood estimator for the drift is intimately linked to the diffusion coefficient, it too is inconsistent between different scales of the data.

The situation is even more complex in the case where data is taken from (5) with $\gamma = 0$, a Hamiltonian ODE – see Figure 4. Again the data is inconsistent at small scales, leading to estimates of drift and diffusion which tend to zero.

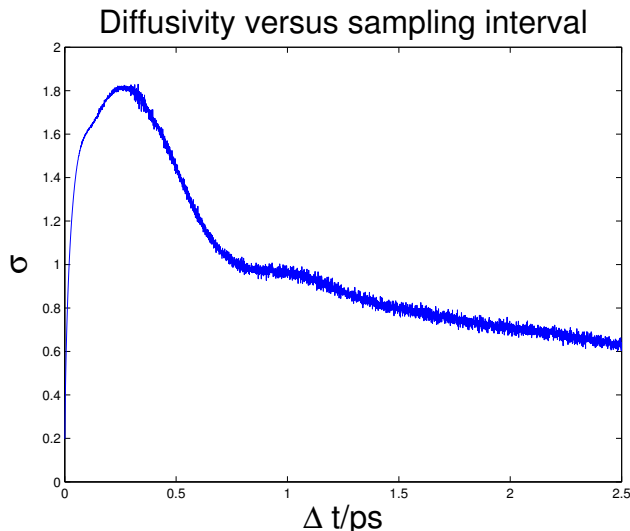

Figure 4: Parameter fits to σ from (6) given data from (5) with $\gamma = 0$

But at intermediate scales oscillations caused by bond length stretches between atoms cause inflated, large diffusion coefficient estimates – a resonance effect.

The erratic behaviour of diffusivity for large inter-sample times might be attributed to the fact that the estimator of diffusivity based on quadratic variation (from (4)) has an error of order $\mathcal{O}(\Delta t)$. However, to see that this is not a major contributor, note that the behaviour of the estimated diffusion coefficient as a function of sampling rate remains qualitatively the same when using a linear Ornstein-Uhlenbeck process

$$\frac{d\Phi}{dt} = -k\Phi + \sigma \frac{dW}{dt} \quad (7)$$

to fit a section of the trajectory of Figure 2 that stays around $\phi = 0$, as can be seen in Figure 5. Here, exact formulae for finite inter-sample time can be used to eliminate Δt effects.

2.4 Example 4. Thermal Motion in a Multiscale Potential

All of the previous examples have the property that the quadratic variation of the data at finest scales is zero, and this is incompatible with the assumed diffusion. Here we present an example (taken from [21]) where, at small scales the quadratic variation of the data is *larger* than that of the desired model to be fitted to the data.

Consider the equation

$$\frac{dx}{dt} = -K^\epsilon(x)\nabla V^\epsilon(x) + \sqrt{2K^\epsilon(x)} \frac{dW}{dt}, \quad (8)$$

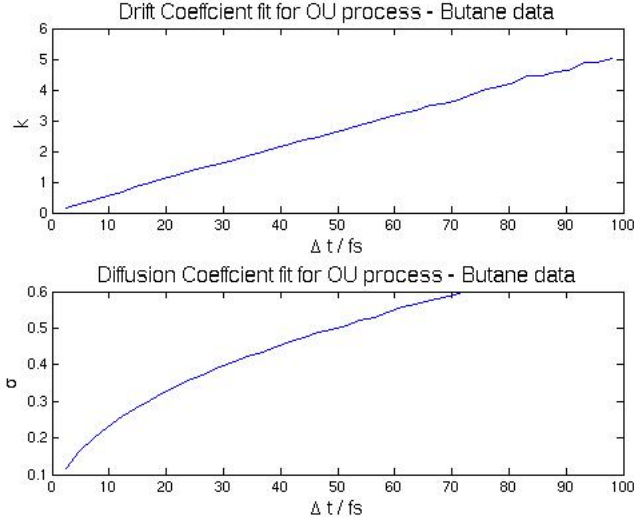

Figure 5: Parameter fits to k and σ from (7) given a section of the data from Figure 2.

where $x \in \mathbb{R}^d$. Here, for K, p 1-periodic functions we define

$$\begin{aligned} K^\epsilon(x) &= K(x/\epsilon), \\ V^\epsilon(x) &= V(x) + p(x/\epsilon). \end{aligned}$$

We also assume that K is symmetric positive-definite, so that its square-root is defined, and divergence-free in the sense that each row of the matrix K is a vector with zero divergence.

By applying standard techniques from homogenization theory it is possible to prove the following theorem:

Theorem 3. [22] As $\epsilon \rightarrow 0$, $x \Rightarrow X$ in $C([0, T], \mathbb{R}^d)$, where X satisfies the equation

$$\frac{dX}{dt} = -\bar{K}\nabla V(X) + \sqrt{2\bar{K}} \frac{dW}{dt}. \quad (9)$$

Furthermore

$$\int_0^T \langle x \rangle_t dt = K^*T, \quad \int_0^T \langle X \rangle_t dt = \bar{K}T; \quad \bar{K} < K^*.$$

Here, $\bar{K} < K^*$ means that $(K^* - \bar{K})$ is positive definite. A typical potential is shown in Figure 6. Notice that the rapid oscillations persist at $\mathcal{O}(1)$ in the limit $\epsilon \rightarrow 0$. Thus, although the oscillatory part of the potential, p , is not present in the homogenized equation, its effect is felt in slowing down the diffusion process, as the particle must cross the energy barriers caused by this oscillation.

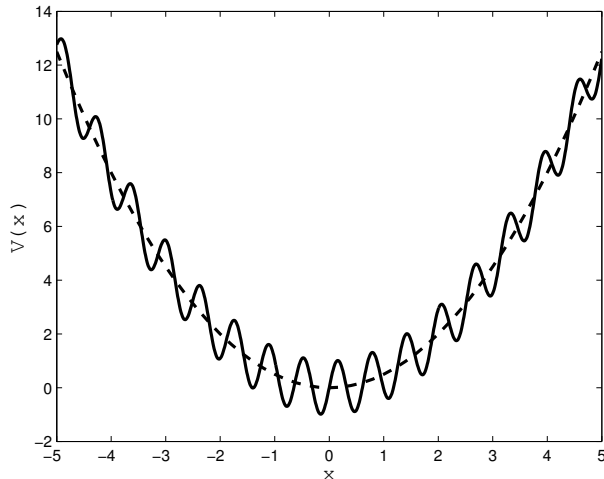

Figure 6: $V^\epsilon(x)$ and $V(x)$.

Once again we expect that parameter estimation which sees the small scales will fail. However the situation differs from the three previous examples: here the quadratic variation of the data x is *larger* than that of the desired homogenized model X .

3 Averaging and Homogenization

3.1 Orientation

In this section we probe the phenomenon exhibited in the preceding examples by means of the study of scale-separated SDEs. These provide us with a set of model problems which can be used to study the issues arising when there is a mismatch between the statistical model and the data at small scales. The last example in the preceding section illustrates such a model problem. Many coupled systems for (x, y) contain a parameter $\epsilon \ll 1$ which characterizes scale-separation. If y evolves more quickly than x then it can sometimes be eliminated to produce an equation for $X \approx x$ alone. Two important situations where this arises are *averaging* and *homogenization*. We will be interested in fitting parameters in an effective averaged or homogenised equation for X , given data x from the coupled system for x, y . All proofs from this section may be found in the paper [19].

3.2 Set-Up

In the following we set $\mathcal{X} = \mathbb{T}^l$ and $\mathcal{Y} = \mathbb{T}^{d-l}$. Let $\varphi_\xi^t(y)$ denote the Markov process which solves the SDE

$$\frac{d}{dt} \left(\varphi_\xi^t(y) \right) = g_0(\xi, \varphi_\xi^t(y)) + \beta(\xi, \varphi_\xi^t(y)) \frac{dV}{dt}, \quad \varphi_\xi^0(y) = y. \quad (10)$$

Here $\xi \in \mathcal{X}$ is a fixed parameter and, for each $t \geq 0$, $\varphi_\xi^t(y) \in \mathcal{Y}$, $g_0 : \mathcal{X} \times \mathcal{Y} \rightarrow \mathbb{R}^{d-l}$, $\beta : \mathcal{X} \times \mathcal{Y} \rightarrow \mathbb{R}^{(d-l) \times m}$ and V is a standard m -dimensional Brownian motion. The generator of the process is

$$\mathcal{G}_0(\xi) = g_0(\xi, y) \cdot \nabla_y + \frac{1}{2} B(\xi, y) : \nabla_y \nabla_y \quad (11)$$

with $B(\xi, y) := \beta(\xi, y)\beta(\xi, y)^T$ and equipped with periodic boundary conditions. Notice that \mathcal{G}_0 is a differential operator in y alone.

Our interest is in data generated by the projection onto the x coordinate of systems of SDEs for (x, y) in $\mathcal{X} \times \mathcal{Y}$. In particular, for U a standard Brownian motion in \mathbb{R}^n we will consider either of the following coupled systems of SDEs:

$$\frac{dx}{dt} = f_1(x, y) + \alpha_0(x, y) \frac{dU}{dt} + \alpha_1(x, y) \frac{dV}{dt}, \quad (12a)$$

$$\frac{dy}{dt} = \frac{1}{\epsilon} g_0(x, y) + \frac{1}{\sqrt{\epsilon}} \beta(x, y) \frac{dV}{dt}; \quad (12b)$$

or the SDEs

$$\frac{dx}{dt} = \frac{1}{\epsilon} f_0(x, y) + f_1(x, y) + \alpha_0(x, y) \frac{dU}{dt} + \alpha_1(x, y) \frac{dV}{dt}, \quad (13a)$$

$$\frac{dy}{dt} = \frac{1}{\epsilon^2} g_0(x, y) + \frac{1}{\epsilon} g_1(x, y) + \frac{1}{\epsilon} \beta(x, y) \frac{dV}{dt}. \quad (13b)$$

Here $f_i : \mathcal{X} \times \mathcal{Y} \rightarrow \mathbb{R}^l$, $\alpha_0 : \mathcal{X} \times \mathcal{Y} \rightarrow \mathbb{R}^{l \times n}$, $\alpha_1 : \mathcal{X} \times \mathcal{Y} \rightarrow \mathbb{R}^{l \times m}$, $g_1 : \mathcal{X} \times \mathcal{Y} \rightarrow \mathbb{R}^{d-l}$ and g_0, β are as above. Note that in (12) (resp. (13)) the equation for y with x frozen has solution $\varphi_x^{t/\epsilon}(y(0))$ (resp. $\varphi_x^{t/\epsilon^2}(y(0))$ with $g_1 = 0$). Of course x is not frozen, but since it evolves much more slowly than y , intuition based on freezing x and considering the process (10) is useful. In addition to the generator \mathcal{G}_0 , we also define the operator \mathcal{G}_1 as follows:

$$\mathcal{G}_1 = f_0 \cdot \nabla_x + g_1 \cdot \nabla_y + C : \nabla_y \nabla_x,$$

where the matrix-valued function C is defined as

$$C(x, y) = \alpha_1(x, y)\beta(x, y)^T.$$

Assumptions 1. • All the functions f_i, g_i, α_i and β are C^∞ on the torus \mathbb{T}^d .

- The equation

$$-\mathcal{G}_0^*(\xi)\rho(y; \xi) = 0, \quad \int_{\mathcal{Y}} \rho(y; \xi) dy = 1$$

has a unique non-negative solution $\rho(y; \xi) \in L^1(\mathcal{Y})$ for every $\xi \in \mathcal{X}$; furthermore $\rho(y; \xi)$ is C^∞ in y and ξ .

- Define the weighted Hilbert space $L_\rho^2(\mathcal{Y})$ with inner-product

$$\langle a, b \rangle_\rho := \int_{\mathcal{Y}} \rho(y; \xi) a(y) b(y) dy.$$

The Poisson equation

$$-\mathcal{G}_0(\xi)\Theta(y; \xi) = h(y; \xi), \quad \int_{\mathcal{Y}} \rho(y; \xi)\Theta(y; \xi) dy = 0$$

has a unique solution $\Theta(y; \xi) \in L_\rho^2(\mathcal{Y})$, provided that

$$\int_{\mathcal{Y}} \rho(y; \xi) h(y; \xi) dy = 0.$$

- If $h(y; \xi)$ and all its derivatives with respect to y, ξ are uniformly bounded in $\mathcal{X} \times \mathcal{Y}$ then the same is true of Θ solving the Poisson equation above.

The second assumption is an ergodicity assumption. It implies the existence of an invariant measure $\mu_\xi(dy) = \rho(y; \xi) dy$ for $\varphi_\xi^t(\cdot)$. From the Birkhoff ergodic theorem it follows that, for μ -almost all $y \in \mathcal{Y}$,

$$\lim_{T \rightarrow \infty} \frac{1}{T} \int_0^T \phi(\xi, \varphi_\xi^t(y)) dt = \int_{\mathcal{Y}} \phi(\xi, y) \rho(y; x) dy.$$

The averaging and homogenization theorems we now state arise from the calculation of appropriate averages against the measure $\mu_x(dy)$.

3.3 Averaging

Define $F(x)$ by

$$F(x) = \int_{\mathcal{Y}} f_0(x, y) \rho(y; x) dy$$

and $\Sigma(x)$ to be the matrix satisfying

$$2\Sigma(x) = \int_{\mathcal{Y}} (\alpha_0(x, y)\alpha_0(x, y)^T + \alpha_1(x, y)\alpha_1(x, y)^T) \rho(y; x) dy.$$

We note that $\Sigma(x)$ is positive semidefinite and hence its square root is well-defined.

Theorem 4. [19] *Let Assumptions 1 hold. Then $x \Rightarrow X$ in $C([0, T], \mathcal{X})$ where X solves the SDE*

$$\frac{dX}{dt} = F(X) + \sqrt{2\Sigma(X)} \frac{dW}{dt} \quad (14)$$

with W a standard l -dimensional Brownian motion.

3.4 Homogenization

In order for the equations (13) to produce a sensible limit as $\epsilon \rightarrow 0$ it is necessary to impose a condition on f_0 . Specifically we assume the following which, roughly, says that $f_0(x, y)$ averages to zero against the empirical measure of the fast y process.

Assumptions 2.

$$\int_{\mathcal{Y}} \rho(y; x) f_0(x, y) dy = 0.$$

Let $\Phi(x, y) \in L^2_{\rho}(\mathcal{Y})$ be the unique solution of the equation

$$-\mathcal{G}_0 \Phi(y; x) = f_0(x, y), \quad \int_{\mathcal{Y}} \rho(y; x) \Phi(y; x) dy = 0.$$

This has a unique solution by Assumptions 1 and 2 (by the Fredholm Alternative). Define

$$F(x) = F_0(x) + F_1(x)$$

where

$$\begin{aligned} F_0(x) &= \int_{\mathcal{Y}} \left((\nabla_x \Phi f_0)(x, y) + (\nabla_y \Phi g_1)(x, y) \right. \\ &\quad \left. + (\alpha_1 \beta^T : \nabla_y \nabla_x \Phi)(x, y) \right) \rho(y; x) dy, \\ F_1(x) &= \int_{\mathcal{Y}} f_1(x, y) \rho(y; x) dy. \end{aligned}$$

Also define $\Sigma(x)$ to be the matrix satisfying

$$2\Sigma(x) = A_1(x) + A_2(x)$$

where

$$\begin{aligned} A_1(x) &= \int_{\mathcal{Y}} \left((\nabla_y \Phi \beta + \alpha_1) (\nabla_y \Phi \beta + \alpha_1)^T \right) (x, y) \rho(y; x) dy, \\ A_2(x) &= \int_{\mathcal{Y}} \alpha_0(x, y) \alpha_0(x, y)^T \rho(y; x) dy. \end{aligned}$$

By construction $\Sigma(x)$ is positive semidefinite and so its square root is well-defined.

Theorem 5. [19] *Let Assumptions 1, 2 hold. Then $x \Rightarrow X$ in $C([0, T], \mathcal{X})$ where X solves the SDE*

$$\frac{dX}{dt} = F(X) + \sqrt{2\Sigma(X)} \frac{dW}{dt} \tag{15}$$

with W a standard l -dimensional Brownian motion.

3.5 Parameter Estimation

Imagine that we try to fit data $\{x(t)\}_{t \in [0, T]}$ from (12) or (13) to a homogenized or averaged equation of the form (14) or (15), but with an unknown parameter θ in the drift:

$$\frac{dX}{dt} = F(X; \theta) + \sqrt{2\Sigma(X)} \frac{dW}{dt}. \quad (16)$$

We assume $\Sigma(X)$ is uniformly positive definite on \mathcal{X} . Suppose that the actual drift compatible with the data is given by $F(X) = F(X; \theta_0)$. We ask whether it is possible to correctly identify $\theta = \theta_0$ by finding the *maximum likelihood estimator* (MLE) when using a statistical model of the form (16), but given data from (12) or (13). We assume that (16) is ergodic with invariant measure $\pi(x)$ at $\theta = \theta_0$. This enables us to probe directly the question of how parameter estimators function when the desired model-fit is incompatible with the data at small scales.

Given data $\{z(t)\}_{t \in [0, T]}$, application of the Girsanov theorem shows that the log likelihood for θ satisfying (16) is given by

$$\mathcal{L}(\theta; z) = \int_0^T \langle F(z; \theta), dz \rangle_{\sigma(z)} - \frac{1}{2} \int_0^T |F(z; \theta)|_{\sigma(z)}^2 dt, \quad (17)$$

where

$$\langle r_1, r_2 \rangle_{\sigma(z)} = \frac{1}{2} \langle r_1, \Sigma(z)^{-1} r_2 \rangle.$$

The MLE is a random variable given by

$$\hat{\theta} = \operatorname{argmin}_{\theta} \mathcal{L}(\theta; z).$$

Before analyzing the situation which arises when data and model are incompatible, we first recap the situation that occurs when data is taken from the model used to fit the data, in order to facilitate comparison. The following theorem shows how the log likelihood behaves, for large T , when the data is generated by the model used to fit the data itself.

Theorem 6. [19] *Assume that (16) is ergodic with invariant density $\pi(X)$ at $\theta = \theta_0$, and that $\{X(t)\}_{t \in [0, T]}$ is a sample path of (16) with $\theta = \theta_0$. Then*

$$\begin{aligned} \lim_{T \rightarrow \infty} \frac{2}{T} \mathcal{L}(\theta; X) &= \int_{\mathcal{Y}} |F(Z; \theta_0)|_{\sigma(Z)}^2 \pi(Z) dZ \\ &\quad - \int_{\mathcal{Y}} |F(Z; \theta) - F(Z; \theta_0)|_{\sigma(Z)}^2 \pi(Z) dZ, \end{aligned}$$

where convergence takes place in $L^2(W)$ (square integrable random variables on the probability space for the Brownian motion W) and is almost sure wrt. the initial condition $X(0)$. The above expression is maximized by choosing $\hat{\theta} = \theta_0$.

We make three observations: (i) for large T the likelihood is asymptotically independent of the particular sample path chosen – it depends only on the invariant measure; (ii) as a consequence we see that, asymptotically, time-ordering

of the data is irrelevant to drift parameter estimation – this is something we will exploit in our nonparametric estimation in Section 6; (iii) the large T expression also shows that choosing data from the model which is to be fitted leads to the correct estimation of drift parameters, in the limit $T \rightarrow \infty$.

In the following we make:

Assumptions 3. Equation (12) (resp. (13)) is ergodic with invariant measure $\rho^\epsilon(x, y) dx dy$. This measure converges weakly to the measure $\pi(x) \rho(y; x) dx dy$ where $\rho(y; x)$ is the invariant density of the fast process (10) and $\pi(x)$ is the invariant density for (14) (resp. (15)).

This assumption may be verified under mild assumptions on the drift and diffusion coefficients of the SDEs.

We now ask what happens when the MLE for the averaged equation (16) is confronted with data from the original multiscale equation (12). The following result explains what happens if the estimator sees the small scales of the data and shows that, in the averaging scenario, there is no problem arising from the incompatibility. Specifically the large T and small ϵ limit of the log-likelihood with multiscale data converges to the likelihood arising with data taken from the statistical model itself.

Theorem 7. [19] Let Assumptions 1 and 3 hold. Let $\{x(t)\}_{t \in [0, T]}$ be a sample path of (12) and $X(t)$ a sample path of (16) at $\theta = \theta_0$.

$$\lim_{\epsilon \rightarrow 0} \lim_{T \rightarrow \infty} \frac{1}{T} \mathcal{L}(\theta; x) = \lim_{T \rightarrow \infty} \frac{1}{T} \mathcal{L}(\theta; X),$$

where convergence takes place in the same sense as in Theorem 6.

We now ask what happens when the MLE for the homogenized equation (16) is confronted with data from the original multiscale equation (13). In contrast to the situation with averaging, here there is a problem arising from the incompatibility at small scales. Specifically the large T and small ϵ limit of the log-likelihood with multiscale data differs from the likelihood arising with data taken from the statistical model at the correct parameter value.

In order to state the theorem we introduce the Poisson equation

$$-\mathcal{G}_0 \Gamma = \langle F(x; \theta), f_0(x, y) \rangle_{\sigma(x)}, \quad \int_{\mathcal{Y}} \rho(y; \xi) \Gamma(y; x) dy = 0 \quad (18)$$

which has a unique solution $\Gamma(y; \xi) \in L^2_\rho(\mathcal{Y})$ (as for Φ , by the Fredholm Alternative). Note that

$$\Gamma = \langle F(x; \theta), \Phi(x, y) \rangle_{\sigma(x)}.$$

Then define

$$E = \int_{\mathcal{X} \times \mathcal{Y}} \left(\mathcal{G}_1 \Gamma(x, y) - \langle F(x; \theta), (\mathcal{G}_1 \Phi(x, y)) \rangle_{\sigma(x)} \right) \pi(x) \rho(y; x) dx dy.$$

Theorem 8. *Let Assumptions 1, 2 and 3 hold. Let $\{x(t)\}_{t \in [0, T]}$ be a sample path of (13) and $X(t)$ a sample path of (16) at $\theta = \theta_0$. Then*

$$\lim_{\epsilon \rightarrow 0} \lim_{T \rightarrow \infty} \frac{1}{T} \mathcal{L}(\theta; x) = \lim_{T \rightarrow \infty} \frac{1}{T} \mathcal{L}(\theta; X) + E,$$

where convergence is in the sense given in Theorem 6.

This theorem shows that the correct limit of the log likelihood is not obtained unless \mathcal{G}_1 is a differential operator in y only, in which case we recover the averaging situation covered in the Theorem 4. The paper [19] contains examples in which E can be calculated explicitly. These examples demonstrate that E is non-zero and leads to a bias.

4 Subsampling

In the previous section we demonstrated that, in the situation where homogenization pertains, the use of multiscale data can lead to identification of the incorrect homogenized coefficients. In this section we illustrate the first of three ideas which can be useful in overcoming the fact that data may be incompatible with the desired diffusion at small scales. In words the basic idea is to use subsampling of the data, at an appropriate rate, to ensure that the data is interrogated on a scale where it "behaves like" data from the homogenized equation. This section is based on [21]. Similar ideas relating to the role of subsampling are encountered in the market microstructure noise models discussed in [17].

In the numerical experiments that we will present, the data will be in discrete time: it will be in the form of a sequence $z = \{z_n\}_{n=0}^N$ which we will view as approximating a diffusion process, whose parameters we wish to estimate, at time increment δ . Assuming that the vector field $F(z; A) = AF(z)$ for some scalar $A \in \mathbb{R}$ then the maximum likelihood estimator derived from (17) gives

$$\hat{A} = \frac{\int_0^T \langle F(z), dz \rangle_{\sigma(z)}}{\int_0^T |F(z)|_{\sigma(z)}^2 dt}.$$

A natural discrete time analogue of this estimator, which we will use in this paper, is

$$\hat{A}_{N, \delta}(z) = \frac{\sum_{n=0}^{N-1} \langle F(z_n), z_{n+1} - z_n \rangle_{\sigma(z_n)}}{\sum_{n=0}^{N-1} \delta |F(z_n)|_{\sigma(z_n)}^2}. \quad (19)$$

Although we concentrated in the previous section on drift parameter estimation, in numerical experiments presented here we will also investigate estimation of the diffusion coefficient. Specifically, in the case where Σ is constant, given a discrete time-series $\{z_n\}_{n=0}^N$, we estimate Σ by

$$\hat{\Sigma}_{N, \delta}(z) = \frac{1}{2T} \sum_{j=0}^{N-1} (z_{j+1} - z_j)(z_{j+1} - z_j)^T, \quad (20)$$

where $z_j = z(j\delta)$ and $N = \lfloor \frac{T}{\delta} \rfloor$. This is derived from equation (4).

For our numerical investigations we revisit Example 4 in one dimension. Consider the equation

$$\frac{dx}{dt} = -\alpha \nabla V^\epsilon(x) + \sqrt{2\sigma} \frac{dW}{dt}. \quad (21)$$

Here $V^\epsilon(x) = V(x) + p(x/\epsilon)$ and p is 1-periodic. To write this in the form to which homogenization applies notice that setting $y = x/\epsilon$ we obtain

$$\begin{aligned} \frac{dx}{dt} &= -\alpha \nabla V(x) - \frac{\alpha}{\epsilon} \nabla p(y) + \sqrt{2\sigma} \frac{dW}{dt}, \\ \frac{dy}{dt} &= -\frac{\alpha}{\epsilon} \nabla V(x) - \frac{\alpha}{\epsilon^2} \nabla p(y) + \sqrt{\frac{2\sigma}{\epsilon^2}} \frac{dW}{dt}. \end{aligned}$$

This is now a specific case of (13).

Theorem 3 shows that the homogenized equation is

$$\frac{dX}{dt} = -A \nabla V(X) + \sqrt{2\Sigma} \frac{dW}{dt}. \quad (22)$$

Furthermore, the theorem shows that

$$A < \alpha, \quad \Sigma < \sigma.$$

In fact $A/\Sigma = \alpha/\sigma$. It may be shown that Σ is exponentially small in $\sigma \rightarrow 0$ [3]. Thus the relative discrepancy between the original and homogenized diffusion coefficients is enormous in the small diffusion limit.

The numerical experiments that we now describe concern the case where

$$V(x) = \frac{1}{2}x^2, \quad p(y) = \cos(y).$$

The experiments are conducted in the following way. We generate the data by simulating the multiscale process x using a time-step Δt which is small compared to ϵ^2 so that the data is a fully resolved approximation of the multiscale process. We then use this data in the estimators (19), (20) which are based on a homogenized model. We study two cases: in the first we take data sampled at time-step $\delta = \Delta t$ so that the data is high frequency relative to the small scales in the equation; we anticipate that this scenario should be close to that covered by the theory in the previous section where we take continuous time data as input. We then show what happens if we subsample the data and take a step δ which is comparable to ϵ ; as the fast process has time-scale ϵ^2 the hope is that, on the scale ϵ , which is long compared with ϵ^2 , the data will "look like" that of the homogenized process.

The time-interval used is $t \in [0, 10^4]$ and the data is generated with time-step $\Delta t = 5 \cdot 10^{-4}$. Figure 7 shows the maximum likelihood and quadratic variation estimators (19) and (20), for the drift and diffusion coefficients respectively, with data $z = x$ at the fine-scale $\delta = \Delta t$. The figure clearly shows that the estimators

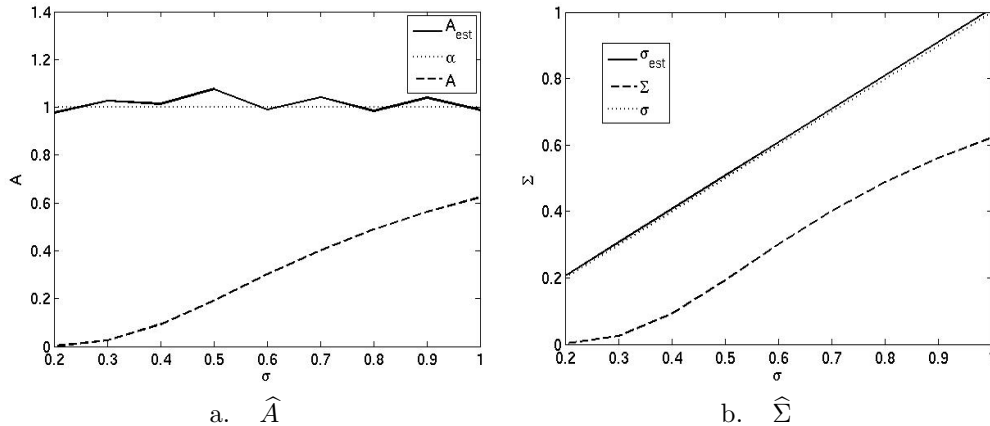

Figure 7: \hat{A} and $\hat{\Sigma}$ vs σ for $\alpha = 1$, $\epsilon = 0.1$

fail to correctly identify coefficients in the homogenized equation (15) for X when employing multiscale data x . Indeed the estimator finds a and σ , from the unhomogenized equation, rather than A and Σ . Hence it overestimates.

Figure 8 shows that, if subsampling is used, this problem may be overcome by interrogating the data at scale ϵ ; this is shown using the time interval $t \in [0, 2 \cdot 10^4]$ and again generating data with a timestep of $\Delta t = 5 \cdot 10^{-4}$, by choosing $\delta = 256 \times \Delta t$, $512 \times \Delta t$ and $\delta = 1024 \times \Delta t$ and showing that, with these choices, the correct parameters are estimated for both drift and diffusion, uniformly over a wide range of σ .

The following theorem justifies the observation that subsampling, at an appropriate rate, results in correct estimators.

Theorem 9. [19] Consider the parameter estimators (19) and (20) for drift and diffusion parameters in the statistical model (22). Define $x = \{x(n\delta)\}_{n=0}^{N-1}$ where $\{x(t)\}$ is a sample path of (21).

- Let $\delta = \epsilon^\alpha$ with $\alpha \in (0, 1)$, $N = \lfloor \epsilon^{-\gamma} \rfloor$, $\gamma > \alpha$. Then

$$\lim_{\epsilon \rightarrow 0} \hat{A}_{N,\delta}(x) = A \quad \text{in distribution.}$$

- Fix $T = N\delta$ with $\delta = \epsilon^\alpha$ with $\alpha \in (0, 1)$. Then

$$\lim_{\epsilon \rightarrow 0} \hat{\Sigma}_{N,\delta}(x) = \Sigma \quad \text{in distribution.}$$

5 Hypocoelliptic Diffusions

In this section we return to the Butane molecule considered in Section 2.3. In that example we showed problems arising from trying to fit a scalar diffusion

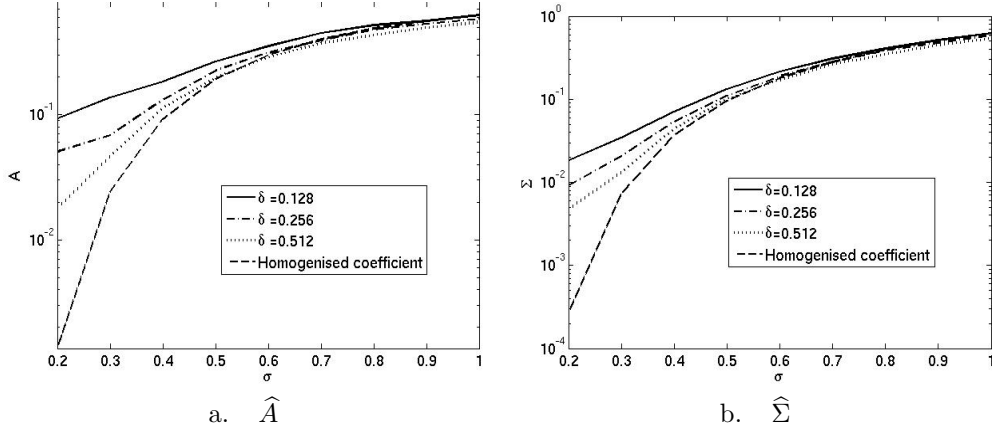

Figure 8: \hat{A} and $\hat{\Sigma}$ vs σ for $a = 1$, $\epsilon = 0.1$. $\delta \in \{0.128, 0.256, 0.512\}$

to the raw time series data from the dihedral angle. Amongst several problems with the attempted fit, we highlighted the fact that the data came from a time series with zero quadratic variation, derived as a nonlinear function of the time-series $x(t)$ from (5), whilst the equation (6) which we attempted to fit had non-zero quadratic variation. In this section we show how we may attempt to overcome this problem by fitting a *hypoelliptic diffusion process* to the dihedral angle data. Technical details can be found in the paper [25].

Specifically we attempt to fit to the data $\{\phi_n\}_{n=0}^N$ a model of the form

$$\frac{d^2\Phi}{dt^2} + \gamma \frac{d\Phi}{dt} - \Psi'(\Phi) = \sigma \frac{dW}{dt}, \quad (23)$$

$$\Psi(\phi) = \sum_{j=1}^5 \frac{\theta_j}{j} (\cos(\phi))^j,$$

The statistical task at hand is then to use discretely observed data $\Phi_i = \Phi(i\delta)$ for some fixed timescale of observation Δt which is assumed to be small to infer the value of the parameters $\{\theta_j\}_{j=1}^5$ as well as γ and σ .

This task is problematic because

1. observations of only ϕ rather than ϕ and its time derivative $\frac{d\phi}{dt}$ are assumed to be available, so a missing data problem is to be dealt with;
2. the two components of the process, namely ϕ and $\frac{d\phi}{dt}$ have different smoothness rendering straightforward statistical models ill-conditioned.

Velocities for ϕ may be available in practice (molecular dynamics codes can certainly produce such output if desired) but it may be preferable to ignore them – such data may be incompatible with SDE models.

It should be emphasized that both the missing data aspect (1 above) and the different degrees of differentiability (2 above) are serious problems *regardless* of whether a frequentist or a Bayesian approach is developed. For simplicity, we will explain these problems further using the maximum likelihood principle and only later introduce a full (Bayesian) estimation algorithm.

In order to better understand these problems we rewrite (23) as a damped-driven Hamiltonian system as follows:

$$dq = p dt, \quad (24a)$$

$$dp = \left(-\gamma p - \sum_{j=1}^5 \theta_j \sin(q) \cos^{j-1}(q) \right) dt + \sigma dB. \quad (24b)$$

where we have used new variables $q(t) = \Phi(t)$ and $p(t) = \frac{d\Phi}{dt}$. To understand how the two problems 1 and 2 enumerated above come about, consider one of the most widespread discrete time approximations to this SDE, the Euler-Maruyama approximation:

$$Q_{i+1} = Q_i + \delta P_i \quad (25a)$$

$$P_{i+1} = P_i - \left(\gamma P_i + \sum_{j=1}^5 \theta_j \sin(Q_i) \cos^{j-1}(Q_i) \right) \delta + \sigma \sqrt{\delta} \xi_i \quad (25b)$$

where $\xi_i \sim \mathcal{N}(0,1)$ is a sequence of iid. standard normal random variables. Using this approximation to estimate σ given the data $\{\phi_n\}_{n=0}^N$ for $\{Q_i\}_{i=0}^N$ and no data for $\{P_i\}_{i=0}^N$ leads to gross mis-estimation. In fact for the simpler example of stochastic growth

$$\begin{aligned} dq &= p dt \\ dp &= \sigma dB \end{aligned}$$

it is straightforward to show that in the limit of infinitely many observations (even for finite δ) the maximum likelihood estimator $\hat{\sigma}$ converges to an incorrect estimate almost surely:

$$\hat{\sigma}^2 \longrightarrow \frac{2}{3} \sigma^2 \quad \text{a.s.}$$

This failure can be traced back to the fact that (25) effectively uses numerical differentiation of the time series Q_i to solve the missing data problem, i.e. to estimate P_i . This approximation neglects noise contributions of order $\mathcal{O}(\delta^{\frac{3}{2}})$ in the first row of (25) which are of the same order as the contributions obtained via numerical differentiation of Q_i .

Understanding the source of the error suggests that replacing the Euler-Maruyama scheme with a higher order discretisation scheme that propagates noise to both rows of the equation (24) results in successful estimators for σ . One such scheme is given by

$$\begin{bmatrix} Q_{i+1} \\ P_{i+1} \end{bmatrix} = \begin{bmatrix} Q_i \\ P_i \end{bmatrix} + \Delta t \begin{bmatrix} P_i \\ \sum_{j=1}^5 \theta_j \sin(Q_i) \cos^{j-1}(Q_i) - \gamma P_i \end{bmatrix} + \sigma \sqrt{\Delta t} R \begin{bmatrix} \xi_1 \\ \xi_2 \end{bmatrix} \quad (26)$$

where the matrix R is given as

$$R = \begin{bmatrix} \frac{\Delta t}{\sqrt{12}} & \frac{\Delta t}{2} \\ 0 & 1 \end{bmatrix} \quad (27)$$

and ξ_1 and ξ_2 are again independent standard normal random variables. Generally, Itô-Taylor expansions of sufficiently high order should be used to propagate noise to all components of the process.

The approximation (26) can be used not only to infer σ but also to infer the missing component of the path.

Finally, it remains to estimate the drift parameters $\{\theta_j\}_{j=1}^5$ and γ and it turns out that the approximation (26) yields results with a large bias that does not decay as Δt decreases or the observation time T increases. In fact, for the simpler case of a harmonic oscillator

$$\begin{cases} dq &= p dt \\ dp &= -\theta q dt - \gamma p dt + \sigma dB. \end{cases} \quad (28)$$

it is possible to compute by Itô-expansion that the maximum likelihood estimator for θ and γ based on an analogous model to (26) satisfies:

$$\begin{aligned} \mathbb{E}\hat{\theta} &= \frac{1}{4}\theta + \mathcal{O}(\Delta t) \\ \mathbb{E}\hat{\gamma} &= \frac{1}{4}\gamma + \mathcal{O}(\Delta t). \end{aligned}$$

This can be traced back to the fact that such an estimator assumes the drift parameters in the first row of (28) to be known exactly whereas the discrete time path only satisfies (26) (or the analogous model for the harmonic oscillator) approximately. The ill-conditioning of the inverse of the matrix R introduced in (27) as $\Delta t \rightarrow 0$ causes small errors to be amplified to $\mathcal{O}(1)$ deviations in the drift parameter estimates. Using the Euler-Maruyama approximation (25) instead delivers satisfactory results.

Having used a maximum likelihood framework to highlight both the fact that the missing data problem adds significant difficulty and that the different degrees of differentiability of ϕ and $\frac{d\phi}{dt}$ produce ill-conditioning, we now proceed to a Bayesian algorithm to infer the missing data $\{P_j\}_{j=0}^N$ as well as the diffusion and drift parameters σ and $\{\theta_j\}_{j=1}^5$ and γ . The sequential Gibbs algorithm suggested to produce approximate samples $\gamma^{(i)}$, $\{\theta_j^{(i)}\}_{j=1}^5$, $\sigma^{(i)}$ and $P_n^{(i)}$ indexed by $i = 1, 2, \dots$ thus reads as follows:

1. Sample $\theta^{(i+1)}, \gamma^{(i+1)}$ from $\mathbb{P}(\{\theta_j\}_{j=1}^5, \gamma | \{Q_j\}_{j=0}^N, \{P_j^{(i)}\}_{j=0}^N, \sigma^{(i)})$ using (25).
2. Sample $\sigma^{(i+1)}$ from $\mathbb{P}(\sigma | \{Q_j\}_{j=0}^N, \{P_j^{(i)}\}_{j=0}^N, \{\theta_j^{(i+1)}\}_{j=1}^5, \gamma^{(i+1)})$ using (26).
3. Sample $\{P_j^{(i+1)}\}_{j=0}^N$ from $\mathbb{P}(\{P_j\}_{j=0}^N | \{Q_j\}_{j=0}^N, \{\theta_j^{(i+1)}\}_{j=1}^5, \gamma^{(i+1)}, \sigma^{(i+1)})$ using (26).

Note that we have omitted the initialisation stage and that sampling the missing path, stage 3, is simplified by the fact that p only ever enters the SDE linearly, so that a direct Gaussian sampler can be used. Stage 1 is also Gaussian, whereas stage 2 is not and an MCMC method, for example, can be used.

The status of Gibbs samplers, such as this one, combining different approximate likelihoods, especially in the presence of ill-conditioning which renders some approximations unsuitable for some of the estimation tasks, is not yet theoretically understood. In the particular case of the SDE being fitted the method has been subjected to very careful numerical studies detailed in [25] and found to be convergent.

Finally, the method can be applied to the data given as Example 3 in Section 2.3 and Figure 9 shows posterior mean parameter estimates as a function of sampling interval δ .

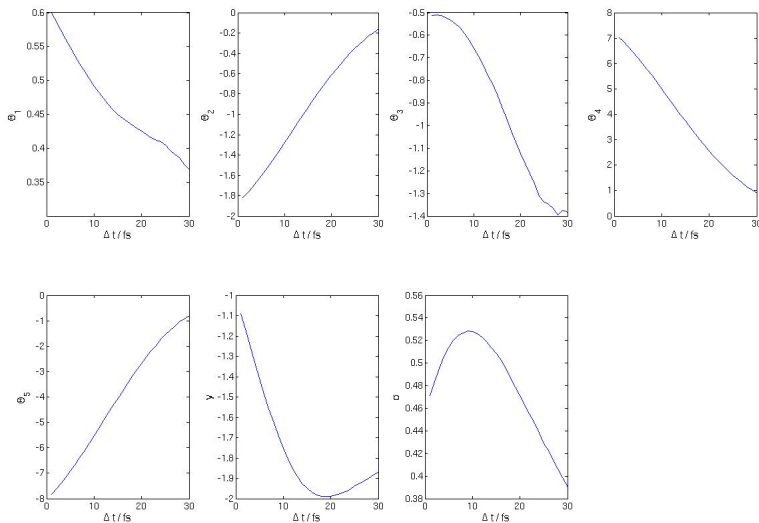

Figure 9: Mean posterior estimates for drift and diffusion parameters using Butane data as a function of sampling interval Δt

We have shown in this section how to extend parameter estimation from the elliptic case (6) to the hypoelliptic case (23) and we have highlighted how to do this in the case of missing velocities. This is useful e.g. when neglecting the velocities is viewed as a means to decrease the fitting process' sensitivity to incompatibility between the model and the data at the short timescales. Still, Figure 9 shows that the fitted drift and diffusion parameters are far from independent of the timescale on which we look at the data. It is natural to

ask why this is so. Since the dihedral angle is a nonlinear transformation of the cartesian coordinates in (5) and hence (as a brief application of the Itô formula readily shows) will exhibit multiplicative rather than additive noise, it will *not* be well-described by a hypoelliptic diffusion with constant diffusivity. It is this problem with model fit that results in the timescale dependence of fitted parameters evidenced in Figure 9.

6 Nonparametric Drift Estimation

Theorem 6 illustrates the fact that, for large times, drift parameter estimation does not see path properties of the data, but rather just sees the invariant measure. This suggests an approach to drift parameter estimation which exploits this property directly and uses only the empirical measure of the data, thereby avoiding issues relating to incompatibility at small scales. These ideas are pursued in [24] and then, building on this in a Bayesian context, in [18].

Here we illustrate the basic ideas in the context of the one-dimensional equation

$$\frac{dx}{dt} = -V'(x) + \frac{dW}{dt}. \quad (29)$$

In [24] we treat the multidimensional case, matrix diffusion coefficients and the second order Langevin equation. We note for later use that the SDE (29) has invariant measure with density

$$\rho \propto \exp(-2V), \quad (30)$$

provided $\exp(-2V) \in L^1(\mathbb{R})$.

Our strategy is a non-parametric one. We write down the log likelihood for this equation which, from (17), has the form

$$\mathcal{L}(V; x) = - \int_0^T V'(x) dx - \frac{1}{2} \int_0^T |V'(x)|^2 dt. \quad (31)$$

Notice that now we view the log likelihood as being a functional of the unknown drift with potential V . This reflects our nonparametric stance. Applying the Itô formula to $V(x(t))$ we deduce that

$$- \int_0^T V'(x) dx = \frac{1}{2} \int_0^T V''(x) dt + (V(x(0)) - V(x(T))).$$

Thus we obtain

$$\mathcal{L}(V; x) = V(x(0)) - V(x(T)) + \frac{1}{2} \int_0^T (V''(x) - |V'(x)|^2) dt. \quad (32)$$

With the goal of expressing the likelihood independently of small-timescale structure of the data we now express the log likelihood in terms of the local time L_T^a of the process. Recall that the local time L_T^a measures the time spent

at a up to time T , so L_T^a/T is proportional to an empirical density function for the path history up to time T . Note that use of the local time L_T^a of the process indeed removes any time-ordering in the data and thus makes drift estimation independent of the dynamical information contained in the data. Since time-ordered data at small scales is at the root of the problems we are confronting in this paper, taking this point of view is likely to be beneficial.

To make the notion of local time as a scaled empirical density rigorous, consider Theorem 2.11.7 in [5] which states that for x being a 1-d continuous semimartingale with local time L_T^a and quadratic variation process $\langle x \rangle_t$, the following identity holds for any Borel-measurable, bounded function g :

$$\int_{-\infty}^{\infty} L_T^a g(a) da = \int_0^T g(x_s) d\langle x \rangle_s. \quad (33)$$

Note that for the process (29) we have

$$dt = d\langle x \rangle_t$$

so that

$$\int_{-\infty}^{\infty} L_t^a g(a) da = \int_0^t g(x_s) ds.$$

In terms of the local time we have

$$\mathcal{L}(V; x) = - (V(x(T)) - V(x(0))) + \frac{1}{2} \int_{\mathbb{R}} (V''(a) - |V'(a)|^2) L_T^a da. \quad (34)$$

To make the mathematical structure of this functional more apparent, we re-express the likelihood in terms of the drift function $b = -V'$. To do this, we first introduce the signed indicator function

$$\tilde{\chi}(a; X_0, X_T) = \begin{cases} 1 & \text{if } X_0 < a < X_T \\ -1 & \text{if } X_T < a < X_0 \\ 0 & \text{otherwise} \end{cases}.$$

The expression for the likelihood then takes the following form:

$$\mathcal{L}(V; x) = -\frac{1}{2} \int_{\mathbb{R}} ((|V'(a)|^2 - V''(a)) L_T^a + 2\tilde{\chi}(a; X_0, X_T)V'(a)) da.$$

Having eliminated V by expressing everything in terms of its derivatives, we replace those derivatives by the drift function b as planned. We abuse notation and now write \mathcal{L} as a functional of b instead of V :

$$\mathcal{L}(b; x) = -\frac{1}{2} \int_{\mathbb{R}} (b^2(a)L_T^a + b'(a)L_T^a - 2\tilde{\chi}(a; X_0, X_T)b(a)) da. \quad (35)$$

We would like to apply the likelihood principle to $\mathcal{L}(b; x)$ and if L_T^a were differentiable in a then an integration by parts on the second term in the integrand above would show that $\mathcal{L}(b; x)$ is bounded above. However, it can be shown that,

in one dimension, the local time L_t^a is jointly continuous in (t, a) , but that it is not in general differentiable; it is only α -Hölder continuous up to but excluding exponent $\alpha = 1/2$. Therefore, the likelihood functional in (35) would not be expected to be bounded above. To get an idea of why this is, consider the case where local time is replaced by a Brownian bridge (which has essentially the same Hölder regularity as local time) where it is possible to show the following theorem (see appendix):

Theorem 10. *Let $w \in C([0, 1], \mathbb{R})$ be a realisation of the standard Brownian bridge on $[0, 1]$. Then with probability one, the functional*

$$I(b; w) = -\frac{1}{2} \int_0^1 (b^2(s)w(s) + b'(s)w(s)) ds.$$

is not bounded above for $b \in H^1([0, 1])$.

If $\mathcal{L}(b; x)$ given by (35) is not bounded above then application of the maximum likelihood principle will fail. To remedy this problem, several options are available. One can introduce a parameterisation $b(x, \theta)$ for $\theta \in \Theta \subset \mathbb{R}^m$ for some finite m with the attendant problems of choosing a set of basis functions that make the parameters well-conditioned and easy to interpret. Alternatively, one can work with a mollified version of the local time, \tilde{L}_T^a , which is smooth enough to ensure existence of a maximizer of the likelihood functional. Finally, it is possible to use Tikhonov regularisation and then, taking this further, to adopt a Bayesian framework and use a prior to ensure sufficient regularity. In Section 6.1, we will investigate the use of mollified local time in detail and in Section 6.2 we briefly introduce the Bayesian nonparametric approach.

6.1 Mollified Local Time

To start using mollified local time, we proceed in three steps adopting a traditional regularisation and truncation approach. Firstly, in (35) we replace L_T^a by a mollification \tilde{L}_T^a which is assumed to be compactly supported and non-negative just like the original local time. Additionally, we assume that it has Sobolev regularity $L_T \in H^1(\mathbb{R})$. Secondly, we integrate by parts exploiting the smoothness and compact support of \tilde{L}_T^a :

$$\mathcal{L}(b; x) \approx -\frac{1}{2} \int_{\mathbb{R}} \left(b^2(a) \tilde{L}_T^a - b(a) \left(\tilde{L}_T^a \right)' - 2\tilde{\chi}(a; X_0, X_T) b(a) \right) da \quad (36)$$

Thirdly, we restrict attention to a bounded open interval $U \subset \mathbb{R}$ on the real line which is chosen such that

$$\exists \epsilon > 0 \forall a \in U : \tilde{L}_T^a > \epsilon. \quad (37)$$

This leads to the final approximation of $\mathcal{L}(b; x)$ by the following functional:

$$\tilde{\mathcal{L}}(b; x) = -\frac{1}{2} \int_U \left(b^2(a) \tilde{L}_T^a - b(a) \left(\tilde{L}_T^a \right)' - 2\tilde{\chi}(a; X_0, X_T) b(a) \right) da \quad (38)$$

This functional is quadratic in b and it is straightforward to prove the following theorem:

Theorem 11. *The functional $\tilde{\mathcal{L}}(b; x)$ is almost surely bounded above on $b \in L^2(U)$ and its maximum is attained at*

$$\hat{b} = \frac{1}{2} \left(\log \tilde{L}_T^a \right)' - \frac{\tilde{\chi}(a; X_0, X_T)}{\tilde{L}_T^a} \quad (39)$$

Proof. We rewrite the mollified likelihood functional by completing the square as follows:

$$\tilde{\mathcal{L}}(b; x) = -\frac{1}{2} \int_U \left[\left(b - \frac{\left(\tilde{L}_T^a \right)'}{2\tilde{L}_T^a} - \frac{\tilde{\chi}(a; X_0, X_T)}{\tilde{L}_T^a} \right)^2 \tilde{L}_T^a \right. \quad (40)$$

$$\left. - \left(\frac{\left(\tilde{L}_T^a \right)'}{2\tilde{L}_T^a} + \frac{\tilde{\chi}(a; X_0, X_T)}{\tilde{L}_T^a} \right)^2 \tilde{L}_T^a \right] da \quad (41)$$

Observe that the first summand in the integrand is always non-negative. To avoid potentially subtracting two infinite terms from each other, we verify that the second summand in the integrand has a finite integral:

$$\begin{aligned} \int_U \left(\frac{\left(\tilde{L}_T^a \right)'}{2\tilde{L}_T^a} + \frac{\tilde{\chi}(a; X_0, X_T)}{\tilde{L}_T^a} \right)^2 \tilde{L}_T^a da &= \int_U \frac{1}{\tilde{L}_T^a} \left(\frac{\left(\tilde{L}_T^a \right)'}{2} + \tilde{\chi}(a; X_0, X_T) \right)^2 da \\ &\leq \frac{1}{\epsilon} \int_U \left(\frac{1}{2} \left(\tilde{L}_T^a \right)' + \tilde{\chi}(a; X_0, X_T) \right)^2 da \\ &< \infty \end{aligned}$$

where we have used condition (37) in the penultimate inequality and the fact that U is compact and that \tilde{L}_T is smooth (and hence it and its derivative are square-integrable on U). All that remains is to read off the maximizer (39) from the brackets in (40). \square

The last term in (39) is integrable on U (since \tilde{L} is bounded away from zero on U and U is bounded), the integrated version of that MLE thus reads

$$\hat{V}(a) = -\frac{1}{2} \log \tilde{L}_T^a + \int_{\inf(U)}^a \frac{\tilde{\chi}(s; X_0, X_T)}{\tilde{L}_T^s} ds \quad a \in U.$$

Furthermore we expect that \tilde{L}_T^a scales like $\mathcal{O}(T)$. Thus the first term gives the dominant term in the estimator for large T . Retaining only the first term gives the approximation

$$\hat{V}(a) = -\frac{1}{2} \log \tilde{L}_T^a$$

If we make the reasonable assumption that $\frac{1}{T} \tilde{L}_T^a \rightarrow \rho(a)$ as $T \rightarrow \infty$ where ρ is the invariant measure for the process we deduce that, for this approximation,

$$\lim_{T \rightarrow \infty} \widehat{V}(a) = -\frac{1}{2} \log \rho(a).$$

But the invariant density is given by (30) and so we deduce that, under these reasonable assumptions,

$$\lim_{T \rightarrow \infty} \widehat{V}(a) = V(a)$$

as expected.

6.2 Regularized Likelihood Functional

Another way to regularize the functional (34) is to add a penalty function to the logarithm of the likelihood to obtain

$$\mathcal{L}_p(b; x) = \mathcal{L}(b; x) - \|b - b_0\|_H^2.$$

Here H is a suitable Hilbert subspace and we call b_0 the centre of regularisation. We refer to this procedure as Tikhonov regularisation; in the case $b_0 = 0$ it coincides with the standard usage – see [10]. If the additional term $\|b - b_0\|_H^2$ is chosen to penalize roughness it is possible to ensure that the combined logarithm has a unique maximum. Since the penalisation is quadratic, this may be linked to the introduction of a Gaussian prior. The posterior can be shown to be Gaussian, too, because the likelihood is quadratic in b , and all densities and probabilities arising can be given a fully rigorous interpretation. We leave technical and implementation details to [18] and merely outline the key calculations first concentrating on the viewpoint of the Tikhonov regularisation \mathcal{L}_p of the likelihood functional \mathcal{L} , then introducing the Bayesian viewpoint at the end.

Tikhonov Regularisation

We first state a theorem to show that regularisation using the Hilbert space norm

$$\|b\|_H^2 = 2 \int_{\mathbb{R}} b(a)^2 + (b'(a))^2 + (b''(a))^2 da$$

on the Sobolev space $H = H^2(\mathbb{R})$ is indeed possible:

Theorem 12. *For any fixed $c > 0$, the functional*

$$\mathcal{L}_p(b; x) = \mathcal{L}(b; x) - c \|b - b_0\|_{H^2(\mathbb{R})}^2$$

is almost surely bounded above on $b \in H^2(\mathbb{R})$ for any $b_0 \in H^2(\mathbb{R})$.

Proof. The proof follows along the same lines as the proof of Theorem 13 which will be given in full. \square

Showing that a maximizer exists and that it is the solution of the accompanying Euler-Lagrange equations requires a more detailed analysis which is easier to carry out in the periodic setting. Thus, we henceforth consider Itô SDEs with constant diffusivity on the circle parametrized by $[0, 2\pi]$,

$$dx = b(x)dt + dW, \quad x(0) = x_0 \quad \text{on } [0, 2\pi].$$

The state space of the diffusion process is now compact. Also note that using the circle as a state space introduces another linear term into $\mathcal{L}(b; x)$ so that we now have

$$\mathcal{L}(b; x) = -\frac{1}{2} \int_0^{2\pi} \left(b^2(a)L_T^a + b'(a)L_T^a - 2(M + \tilde{\chi}(a; X_0, X_T))b(a) \right) da, \quad (42)$$

where $M \in \mathbb{Z}$ is the winding number of the process x , i.e. the number of times x has gone around the circle in $[0, T]$.

Let us now consider the Tikhonov regularisation of \mathcal{L} by the H^2 -seminorm as follows:

$$\mathcal{L}_p(b; x) = \mathcal{L}(b; x) - \frac{1}{2} \|b - b_0\|_{H^2}^2 \quad b \in H_{\text{per}}^2([0, 2\pi]), \quad (43)$$

where $H_{\text{per}}^2([0, 2\pi])$ refers to the Sobolev space of twice weakly differentiable periodic functions on $[0, 2\pi]$ and $\|b\|_{H^2} = \int_0^{2\pi} (b''(a))^2 da$. Note that the prefactor $\frac{1}{2}$ in front of the seminorm can be replaced by an arbitrary positive constant, allowing an adjustment of the strength of regularization. To analyse this regularized functional, we separate off its quadratic terms by introducing the bilinear form $q(u, v)$ defined for $u, v \in H_{\text{per}}^2([0, 2\pi])$ as follows:

$$q(u, v) = \frac{1}{2} \int_0^{2\pi} \Delta u(a) \Delta v(a) + u(a) L_T^a v(a) da, \quad (44)$$

where we denote second derivatives by the Laplace operator, $\Delta = \frac{d^2}{da^2}$. Important properties of this bilinear form are given in the following Lemma whose proof is slightly technical and can be found in [18].

Lemma 1. *If the local time L_T is not identically zero on $[0, 2\pi]$, then the form q , defined in (44), is a continuous, coercive, symmetric bilinear form, i.e. there are constants $\alpha, C \in \mathbb{R}_+$ which may depend on L_T but not on u, v such that the following relations hold:*

$$\begin{aligned} \alpha \|u\|_{H^2}^2 &\leq q(u, u) \quad \forall u \in H_{\text{per}}^2([0, 2\pi]) \\ q(u, v) &\leq C \|u\|_{H^2} \|v\|_{H^2} \quad \forall u, v \in H_{\text{per}}^2([0, 2\pi]) \\ q(u, v) &= q(v, u) \quad \forall u, v \in H_{\text{per}}^2([0, 2\pi]) \end{aligned} \quad (45)$$

We now state an analogous theorem to Theorem 11:

Theorem 13. *The functional $\mathcal{L}_p(b)$ defined in (43) is almost surely bounded above on $b \in H_{\text{per}}^2([0, 2\pi])$ and its maximum is attained at $\widehat{b} \in H_{\text{per}}^2([0, 2\pi])$ which is given by the unique weak solution of the boundary value problem*

$$(\Delta^2 + L_T)\widehat{b} = \frac{1}{2}L'_T + M + \tilde{\chi}(\cdot; X_0, X_T) + \Delta^2 b_0 \quad (46)$$

Proof. We present a heuristic calculation first that simply proceeds by completing the square and reading off the answer. We then indicate how this can be approached rigorously. To simplify notation we assume that the centre of regularisation is identically zero: $b_0 = 0$.

$$\begin{aligned} \mathcal{L}_p(b; x) = & -\frac{1}{2} \int_0^{2\pi} \left(b^2(a)L_T^a + (\Delta b(a))^2 + b'(a)L_T^a \right. \\ & \left. - 2(\tilde{\chi}(a; X_0, X_T) + M)b(a) \right) da \end{aligned}$$

To simplify the notation we drop the arguments. To formally derive the maximizer we repeatedly integrate by parts, pretending that the local time is sufficiently regular.

$$\mathcal{L}_p = -\frac{1}{2} \int \left(b(\Delta^2 + L_T)b - b(L'_T + 2(\tilde{\chi} + M)) \right) da$$

We now introduce the abbreviations

$$\mathcal{D} = \Delta^2 + L_T \quad (47)$$

$$c = -\frac{1}{2}L'_T - (\tilde{\chi} + M) \quad (48)$$

and the following notational convention for the square root of the operator \mathcal{D} and its inverse:

$$\begin{aligned} \left| \mathcal{D}^{\frac{1}{2}} u \right|^2 &= \langle u, \mathcal{D}u \rangle & u \in H_{\text{per}}^2([0, 2\pi]) \\ \left| \mathcal{D}^{-\frac{1}{2}} u \right|^2 &= \langle u, \mathcal{D}^{-1}u \rangle & u \in H_{\text{per}}^2([0, 2\pi]), \end{aligned}$$

where $\langle \cdot, \cdot \rangle$ denotes the inner product on the Hilbert space $L^2([0, 2\pi])$. These conventions are intended to make the following calculation more transparent, so we rewrite \mathcal{L}_p first of all:

$$\mathcal{L}_p(b; x) = -\frac{1}{2} \langle b, \mathcal{D}b \rangle - \langle b, c \rangle$$

Now we complete the square

$$\mathcal{L}_p(b; x) = -\frac{1}{2} \left| \mathcal{D}^{\frac{1}{2}} (b + \mathcal{D}^{-1}c) \right|^2 + \frac{1}{2} \left| \mathcal{D}^{-\frac{1}{2}} c \right|^2$$

and note that the maximizer of the regularized functional can be seen to be given by

$$\widehat{b} = -\mathcal{D}^{-1}c.$$

This is identical to (46) which can be seen by inserting the terms from (47) and (48); boundedness from above is also apparent.

We rigorously establish boundedness from above (again in the case $b_0 = 0$) and leave the rest of the proofs to [18]. To do this, we first rewrite the Tikhonov-regularized likelihood using the quadratic form (44) as follows:

$$\mathcal{L}_p(b; x) = \frac{1}{2} \int_0^{2\pi} (-b'(a)L_T^a + 2(M + \tilde{\chi}(a; X_0, X_T))b(a)) da - q(b, b)$$

Now bound the linear term in \mathcal{L}_p as follows:

$$\begin{aligned} & \left| \int_0^{2\pi} b'(a)L_T^a - 2b(a)(M + \tilde{\chi}(a; X_0, X_T))da \right| \\ & \leq \int_0^{2\pi} \epsilon_1 (b'(a))^2 + \frac{1}{\epsilon_1} (L_T^a)^2 + \epsilon_2 b^2(a) + \frac{1}{\epsilon_2} (M + \tilde{\chi}(a; X_0, X_T))^2 da \end{aligned}$$

which holds for any $\epsilon_1, \epsilon_2 \in (0, \infty)$. Now choose $\epsilon = \epsilon_1 = \epsilon_2 < \alpha$ where α is given by (45) from Lemma 1. Exploit coercivity (i.e. (45)) in the following way:

$$\begin{aligned} \mathcal{L}_p(b) & \leq -q(b, b) + \epsilon \|b\|_{H^1}^2 + \frac{1}{\epsilon} \|L_T\|_{L^2}^2 + \frac{1}{\epsilon} \|M + \tilde{\chi}(\cdot; X_0, X_T)\|_{L^2}^2 \\ & \leq -(\alpha - \epsilon) \|b\|_{H^2}^2 + \text{const.} \end{aligned}$$

The case $b_0 \neq 0$ presents mainly notational complications, whereas deriving the PDE (46) requires a little variational calculus and showing existence and uniqueness of its solutions is an application of standard PDE theory given in [18]. \square

Bayesian Viewpoint

In this subsection we show that the Tikhonov regularisation given above underpins the adoption of a Bayesian framework and we briefly outline some speculation concerning the limit $T \rightarrow \infty$.

To introduce a prior, we decompose the space $H_{\text{per}}^2([0, 2\pi])$, into the direct sum of the (one-dimensional) space of constant functions and the space of Sobolev functions with average zero (denoted by $\dot{H}_{\text{per}}^2([0, 2\pi])$):

$$H_{\text{per}}^2([0, 2\pi]) = \{\alpha \mathbf{1} \mid \alpha \in \mathbb{R}\} \oplus \dot{H}_{\text{per}}^2([0, 2\pi]),$$

where we use $\mathbf{1}$ to denote the constant function with value one. We now define the prior measure as the product measure found from Lebesgue measure on the

space of constant functions and the Gaussian measure $\mathcal{N}(b_0, A)$ on the space $\dot{H}_{\text{per}}^2([0, 2\pi])$ where $A = \left(-\frac{d^2}{da^2}\right)^{-2}$ subject to periodic boundary conditions:

$$p_0 = \lambda \otimes \mathcal{N}(b_0, A).$$

This is the prior measure. Note that as this is a degenerate Gaussian, we are using an improper prior. Purely formally, this prior can be written as a density with respect to (non-existing) Lebesgue measure on $H_{\text{per}}^2([0, 2\pi])$:

$$p_0(b) \sim \exp\left(-\frac{1}{2} \int_0^{2\pi} (b - b_0)(a) (\Delta^2(b - b_0))(a) da\right). \quad (49)$$

Having defined a prior we now use the Radon Nikodym derivative $\mathcal{L}(b; x)$ as the likelihood just as before. The posterior measure then follows the Bayes formula:

$$\begin{aligned} & \mathbb{P}(b | \{x_t\}_{t=0}^T) \propto \mathbb{P}(\{x_t\}_{t=0}^T | b) p_0(b) \\ &= \exp\left(-\frac{1}{2} \int_0^{2\pi} L_T^a b^2(a) - b(a) (L_T^a)' - 2b(a) (M + \tilde{\chi}(a; X_0, X_T)) da \right. \\ & \quad \left. - \frac{1}{2} \int_0^{2\pi} (b(a) - b_0(a)) \Delta^2(b(a) - b_0(a)) da\right) \end{aligned}$$

where M again corresponds to the number of times the path $\{x_s\}_{s=0}^T$ winds around the circle. Note that this is just the straightforward product of the likelihood (42) with the prior measure (49). We simplify this expression by considering the case $b_0 = 0$ and by dropping the arguments:

$$\mathbb{P}(b | \{x_t\}_{t=0}^T) \propto \exp\left(-\frac{1}{2} \int_0^{2\pi} |\Delta b|^2 + L_T b^2 - b (L_T' + 2M + 2\tilde{\chi}) da\right).$$

Formally completing the square in the exponent as in the proof of Theorem 13 one finds that this posterior measure is again a Gaussian with formal density

$$\mathbb{P}(b | \{x_t\}_{t=0}^T) \sim \exp\left(-\frac{1}{2} \left| \mathcal{D}^{-\frac{1}{2}} (b + \mathcal{D}^{-1}c) \right|^2 + \frac{1}{2} \left| \mathcal{D}^{-\frac{1}{2}} c \right|^2\right),$$

where we have used the abbreviations (47) and (48) to shorten notation. Its mean is given by (46) and its covariance is

$$C_o = (\Delta^2 + L_T)^{-1}. \quad (50)$$

This establishes the usual connection between regularisation of the likelihood and the mean of an appropriate Bayesian posterior. It is possible to prove existence and robustness of these measures against small errors in the local time, including stability of a numerical implementation, see [18] for details.

Finally, let us rewrite (46) in a suggestive form:

$$\widehat{b} = (\Delta^2 + L_T)^{-1} \left(\frac{1}{2} L_T' + M + \tilde{\chi}(\cdot; X_0, X_T) + \Delta^2 b_0 \right). \quad (51)$$

Heuristically we expect that L_T is $\mathcal{O}(T)$ for large T , and since Δ^2 is $\mathcal{O}(1)$ on low frequencies we expect that equation (50) defines a small operator, at least on low frequencies, and that the covariance of the posterior tends to the zero operator as $T \rightarrow \infty$. Likewise the mean, given by (47), will approach

$$\frac{1}{2} (\log L_T^a)'$$

for large T . Note that we have a similar result for the maximizers of the likelihood for regularized local times, see (39).

In summary, these heuristics indicate that the Bayesian framework should be amenable to a posterior consistency result with the posterior measure converging to a Dirac distribution centered at the true drift function.

7 Conclusions and Further Work

In this overview we have illustrated the following points:

- At small scales, data is often incompatible with the diffusion process that we wish to fit.
- In Section 3 we saw that
 1. this situation can be understood in the context of fitting averaged/homogenized equations to multiscale data,
 2. in the *averaging* situation fine-scale data produces the *correct* averaged equation,
 3. in the *homogenization* situation fine-scale data produces an *incorrect* homogenized equation.
- In Section 4 we saw that
 1. to estimate the drift and diffusion coefficients accurately in the homogenization scenario it is necessary to *subsample*,
 2. there is an optimal subsampling rate, between the two characteristic timescales of the multiscale data,
 3. the optimal subsampling rate may differ for different parameters.
- In Section 5 we observed that in the case where the data is smooth at small scales a useful approach can be to fit hypoelliptic diffusions; such models are often also dictated by physical considerations.

- In Section 6 we observed that when fitting the drift, another approach is to use estimators which do not see time-ordering of the data and use, instead, the *local time* (or empirical measure) of the data.

There are many open questions for further investigation:

Section 3: How to identify multiscale character from time-series?

- Section 4:
1. If subsampling is used, then what is the optimal subsampling rate?
 2. Is subsampling at random helpful?
 3. Is it possible to optimize the data available by combining shifts?
 4. How to estimate diffusion coefficients from low frequency data?

- Section 5:
1. A theoretical understanding of the conditions under which hybrid Gibbs samplers, using different approximate likelihoods for different parts of the sampling problem, yield approximately correct samples from the true posterior is yet to be attained.
 2. While the recipe described in this section extends to higher order hypoellipticity, the method is still to be tested in this region.

- Section 6:
1. How to obtain estimates of the local time L_T^a for all a which are good in a suitable norm, e.g. L^2 ?
 2. What is the convergence behaviour as $T \rightarrow \infty$ for the mollified maximum likelihood and the Bayesian estimators?
 3. How to extend the Bayesian approach to higher dimensions where the empirical measure is even less regular than in the one dimensional case?

Acknowledgements We gratefully acknowledge crucial contributions from all our co-authors on work we cited in this chapter.

8 Appendix

Let us consider the random functional

$$\mathcal{I}(b; w) = \int_0^1 b^2(x)w(x) + b'(x)w(x)dx. \quad (52)$$

where $b(\cdot) \in H^1(0, 1)$ and $w(x)$ is a standard Brownian bridge. We claim that this functional is not bounded below and state this as a theorem:

Theorem 14. *There almost surely exists a sequence $b^{(n)}(\cdot) \in H^1(0, 1)$ such that*

$$\lim_{n \rightarrow \infty} \mathcal{I}(b^{(n)}; w) = -\infty \quad \text{a.s.}$$

Proof. For the Brownian bridge we have the representation

$$w(x) = \sum_{i=1}^{\infty} \frac{\sin(i\pi x)}{i} \xi_i \quad (53)$$

where the $\{\xi_i\}_{i=1}^{\infty}$ are a sequence of iid normal $\mathcal{N}(0, 1)$ random variables. This series converges in $L^2(\Omega; L^2((0, 1), \mathbb{R}))$ and almost surely in $C([0, 1], \mathbb{R})$, see [9].

Now consider the following sequence of functions $b^{(n)}$:

$$b^{(n)}(x) = \sum_{i=1}^n \frac{\xi_i}{i} \cos(i\pi x). \quad (54)$$

We think of a fixed realisation $\omega \in \Omega$ of (53) for the time being and note that $\{w(x) : x \in [0, 1]\}$ is almost surely bounded in $L^\infty((0, 1), \mathbb{R})$, so if there exists a $C > 0$ (which may depend on $\{\xi_i\}_{i=0}^{\infty}$) such that

$$\|b^{(n)}\|_{L^2} < C \quad \forall n \in \mathbb{N} \quad (55)$$

the first integral in (52) will stay finite. By Parseval's identity, it is clear that for the sequence of functionals (54) this will be the case if the coefficients $\frac{\xi_i}{i}$ are square-summable.

Computing the second summand in (52) is straightforward since the series terminates due to orthogonality:

$$\int_0^1 \left(\sum_{i=1}^{\infty} \frac{\sin(i\pi x)}{i} \xi_i \right) \cdot \left(\sum_{j=1}^n \frac{\xi_j}{j} \cos(j\pi x) \right)' dx = -\frac{\pi}{2} \sum_{j=1}^n \frac{\xi_j^2}{j}.$$

It can now be seen that (52) is unbounded from below if the following two conditions are fulfilled:

$$\lim_{n \rightarrow \infty} \sum_{j=1}^n \frac{1}{j} \xi_j^2 = \infty \quad (56)$$

$$\lim_{n \rightarrow \infty} \sum_{j=1}^n \frac{1}{j^2} \xi_j^2 < \infty \quad (57)$$

We finally allow ω to vary and seek to establish that the conditions (56) and (57) are almost surely fulfilled. To do this, first note that the random variables being summed are independent. Thus, by the Kolmogorov 0-1 law the probability for convergence is either zero or one. We proceed by applying Kolmogorov's Three-Series Theorem (theorem 12.5 in [29]) to each of the three sequences to establish (56) and (57).

We start by treating (56). Denote by $X_j |^K$ the truncation of the random variable for some $K > 0$ in the sense:

$$X_j |^K (\omega) = \begin{cases} X_j(\omega) & \text{if } |X_j(\omega)| \leq K \\ 0 & \text{if } |X_j(\omega)| > K \end{cases}.$$

To abbreviate notation, define the following two sequences of random variables:

$$X_j = \frac{1}{j} \xi_j^2$$

$$Y_j = \frac{1}{j^2} \xi_j^2$$

Now consider the summability of expected values for the sequence X_j : since ξ_j^2 follows a χ -squared distribution with one degree of freedom, its expected value is one. For the truncated variable $X_j |^K$, for any $K > 0$, there will be some j^* so that for all $j \geq j^*$ we have that

$$\mathbb{E}(X_j |^K) = \mathbb{E} \left[\frac{1}{j} (\xi^2 |^{jK}) \right] > \frac{1}{2j}$$

Therefore, the expected value summation fails as follows:

$$\begin{aligned} \sum_{j=1}^{\infty} \mathbb{E}(X_j |^K) &= \sum_{j=1}^{\infty} \frac{1}{j} \mathbb{E}(\xi^2 |^{jK}) \\ &\geq \sum_{j=j^*}^{\infty} \frac{1}{2j} = \infty \end{aligned}$$

Therefore, the series $\sum_{j=1}^{\infty} X_j$ diverges to infinity almost surely, thus (56) is established.

Now let us establish (57) using the Three-series theorem. First check the summability of the expected values:

$$\sum_{j=1}^{\infty} \mathbb{E}(Y_j |^K) \leq \sum_{j=1}^{\infty} \mathbb{E}Y_j = \sum_{j=1}^{\infty} \frac{1}{j^2} < \infty$$

Now let us establish the summability of the variances:

$$\begin{aligned} \sum_{j=1}^{\infty} \text{Var}(Y_n |^K) &\leq \sum_{j=1}^{\infty} \text{Var}Y_n \\ &= \sum_{j=1}^{\infty} \frac{1}{j^4} \text{Var}\xi_j^2 \\ &= 2 \sum_{j=1}^{\infty} \frac{1}{j^4} < \infty \end{aligned}$$

where we used that ξ_j^2 follows a χ -squared distribution with one degree of freedom and hence has variance $\text{Var}\xi_j^2 = 2$. Finally, to establish the summability

of the tail probabilities we use the following argument for any $K > 0$:

$$\begin{aligned} \sum_{j=1}^{\infty} P(|Y_j| > K) &\leq \sum_{j=1}^{\infty} \frac{1}{K} \mathbb{E}|Y_j| \\ &\leq \frac{1}{K} \sum_{j=1}^{\infty} \frac{1}{j^2} < \infty \end{aligned}$$

where we have used the Markov inequality and the previous calculation of the expected value of $Y_j = |Y_j|$.

To put everything together let us reconsider the functional $I_B[b]$:

$$\begin{aligned} I_B[b^{(n)}] &= \int_0^1 \left(b^{(n)}\right)^2(x)w(x) + \left(b^{(n)}\right)'(x)w(x)dx \\ &\leq \left(\sup_{x \in [0,1]} w(x)\right) \int_0^1 \left(b^{(n)}\right)^2(x)dx - \frac{\pi}{2} \sum_{j=1}^n \frac{1}{j} \xi_j^2 \\ &\leq \left(\sup_{x \in [0,1]} w(x)\right) \frac{1}{2} \sum_{j=1}^n X_j - \frac{\pi}{2} \sum_{j=1}^n Y_j \end{aligned}$$

Now use the almost surely true convergence and divergence statements (56) and (57) to conclude:

$$\lim_{n \rightarrow \infty} I_B[b^{(n)}] = -\infty \quad \text{a.s.}$$
